Management. Management of supraventricular tachycardia depends on the hemodynamic stability of the child. If the child with supraventricular tachycardia is hemodynamically unstable and intravenous access in not available, immediate cardioversion starting at 0.5 to 1 joule/kg is indicated. If the child does not convert with this initial cardioversion attempt, the energy dose can be doubled up to 2 joules/kg on subsequent attempts. If the child is hemodynamically stable, vagal maneuvers or adenosine, or both, can be attempted initially before cardioversion, depending on the individual case scenario. Regardless of the method selected to convert the supraventricular tachycardia, a continuous rhythm strip should be run to document the response to each conversion attempt. Vagal maneuvers (e.g., a bag containing a slurry of crushed ice and water to the face, blowing on an occluded straw, or blowing on the tip of a syringe) can be attempted before adenosine administration only in the child with hemodynamically stable supraventricular tachycardia. Application of ice to the face has been demonstrated to be a fairly effective method of converting supraventricular tachycardia in infants and children.[44,45] One method to perform this maneuver is to fill a plastic bag or surgical glove with a slurry of crushed ice and water, which is then placed over the infant's forehead, eyes, and bridge of the nose for 10 to 15 seconds. Care must be taken not to occlude the nose or mouth with the bag of ice water. External ocular pressure should be avoided; it can be dangerous in children because excessive pressure can lead to a ruptured globe. Carotid massage is less effective and is not recommended as a vagal maneuver in infants or children.[38]

The initial dose of adenosine in children is 0.1 mg/kg with a maximum initial dose of 6 mg. If this initial dose of adenosine fails to convert the supraventricular tachycardia, the dose is then doubled to 0.2 mg/kg with a maximum of 12 mg/dose. This 0.2 mg/kg dose of adenosine can be attempted once more during the third adenosine dose. Elective cardioversion or esophageal overdrive pacing under conscious sedation may be required in children who fail to convert with adenosine. Asystole and various dysrhythmias, including adenosine-induced wide-complex tachycardia (secondary to an occult accessory conduction pathway), are complications of adenosine administration (Fig. 171-12). The use of verapamil to convert supraventricular tachycardia in infants and younger children should be avoided because of the potential of profound hypotension and cardiovascular collapse when this medication is administered in this age group.[38]

Table 171-8 Clinical and Electrocardiographic Features to Differentiate Sinus Tachycardia from Supraventricular Tachycardia in Children[38]

	SINUS TACHYCARDIA	SUPRAVENTRICULAR TACHYCARDIA
Precipitating events	Dehydration, fever, pain	No precipitating event
P waves on electrocardiogram	Present	Absent
Heart rate varies with activity	Yes	No
Beat-to-beat variability	Yes	Constant R-R intervals
Heart rate in infants (beats/minute)	Usually <220	Usually >220
Heart rate in children (beats/minute)	Usually <180	Usually >180

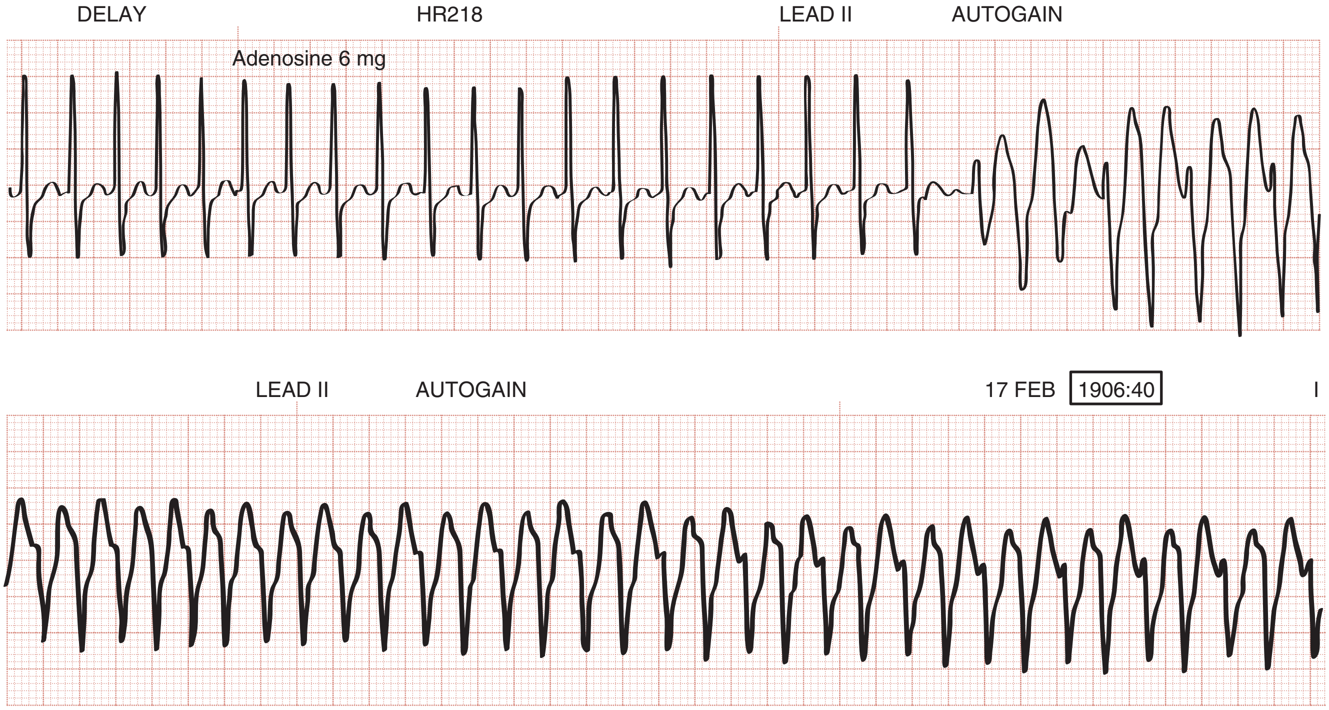

Figure 171-12. An example of adenosine-induced wide-complex tachycardia. A dose of 6 mg of adenosine was administered to this previously healthy 15-year-old girl who presented with a 6-hour history of palpitations. She had no previous cardiac problems except for intermittent palpitations in the past that always resolved spontaneously without any medical interventions. Once adenosine blocked the conduction through the atrioventricular node, a wide-complex tachycardia appeared on the electrocardiogram, which was probably due to antegrade conduction through an accessory pathway. During the 30 seconds of this wide-complex tachycardia, the patient remained alert with excellent perfusion parameters. This wide-complex tachycardia then spontaneously converted to normal sinus rhythm. Although the patient's postconversion electrocardiogram did not reveal an accessory pathway, Holter monitoring 1 month later detected the classic electrocardiographic findings of Wolff-Parkinson-White syndrome.

www.ketabpezeshki.com 66485457-66963820

Once the patient has been converted to sinus rhythm, a 12-lead ECG should be obtained to assess for the possibility of Wolff-Parkinson-White syndrome or any other underlying conduction abnormalities that may have predisposed the child to development of the supraventricular tachycardia.

Atrial Flutter and Atrial Fibrillation. Both atrial flutter and atrial fibrillation are rare in children and are usually associated with underlying heart conditions (i.e., CHD, status post–open heart surgical procedures that involved the atria, myocarditis, and digoxin toxicity). Hemodynamic stability of these two dysrhythmias depends on the rate of the ventricular response. Cardioversion is the treatment of choice for children who present with hemodynamically unstable atrial flutter or atrial fibrillation. The initial treatment priority in patients with hemodynamically stable atrial flutter and atrial fibrillation is first to slow down the rate of the ventricular response with medications such as digoxin, beta-blockers, or diltiazem. Once the ventricular rate is controlled, the rhythm can then be converted and suppressed with amiodarone, procainamide, or elective cardioversion. If the patient who presents with atrial flutter or atrial fibrillation is known to have an underlying Wolff-Parkinson-White syndrome, the four medications that should be avoided are the A-B-C-D medications (adenosine, beta-blockers, calcium channel blockers, and digoxin) because all of these medications preferentially block conduction down the atrioventricular node, leaving the accessory pathway open to conduct the atrial tachycardia to the ventricles at a potentially lethal rate.[45,46] Under these circumstances, amiodarone, procainamide, or cardioversion would be the safer alternative. Consultation with the cardiologist and initiation of anticoagulation should also be considered to prevent a thromboembolic complication before conversion of either of these atrial dysrhythmias in the hemodynamically stable patient believed to have the rhythm disorder 48 to 72 hours before presentation.

Ventricular Tachycardia. Ventricular tachycardia is not a common dysrhythmia in children. The majority of children with ventricular tachycardia have an underlying condition, such as post–cardiac surgery status, myocarditis, prolonged QT syndrome, drug or toxin exposures (e.g., cyclic antidepressants), or electrolyte abnormalities. The treatment of ventricular tachycardia will depend on whether a pulse is present and on the hemodynamic status of the patient (Box 171-14). Torsades de pointes is a unique type of polymorphic ventricular tachycardia characterized by QRS complexes that change in polarity and amplitude. Prolonged QT syndrome, underlying congenital cardiac defects, hypomagnesemia, and various medications (e.g., cyclic antidepressants) have been identified as known causes of torsades de pointes. The treatment of choice is intravenous magnesium. Class IA (i.e., procainamide) and class III (i.e., amiodarone) antidysrhythmic agents are contraindicated in the treatment of torsades de pointes because these two antidysrhythmic agents are capable of prolonging the QT interval, which could then precipitate the degeneration of the torsades de pointes into a more lethal rhythm.

Box 171-14 Clinical Conditions in Which Bacterial Endocarditis Should Be Suspected in a Child with an Underlying Anatomic Cardiac Defect

- Fever of unknown etiology
- A change in the quality of the preexisting heart murmur or the presence of a new heart murmur
- Development of a neurologic deficit (secondary to central nervous system emboli)
- New-onset microscopic hematuria
- Splenomegaly
- Petechiae
- Splinter hemorrhages involving the conjunctiva, nail beds, palms, or soles
- Myalgias

Pulseless Rhythms

Ventricular Fibrillation and Pulseless Ventricular Tachycardia. Ventricular fibrillation and pulseless ventricular tachycardia account for approximately 9 to 10% of out-of-hospital cardiac arrest cases in which a terminal rhythm was recorded.[47,48] The survival rate for out-of-hospital ventricular fibrillation and pulseless ventricular tachycardia can be as high as 30%, whereas the survival rate from asystolic cardiac arrest is less than 1%.[35] In a study of in-hospital cardiac arrests, a shockable rhythm was present during some point of the resuscitation in 25% of the children.[49] The survival rate of children who initially exhibited shockable rhythms was higher than that of those children who presented with nonshockable rhythms. However, the survival rates in those children who later had a shockable rhythm at some time during their resuscitation were not as favorable.[49-51] Ventricular fibrillation should also be suspected as the arrest rhythm in cases of commotio cordis or in cases of sudden cardiac arrest. Current arrhythmia detection algorithms for automated external defibrillators (AEDs) appear to have a high sensitivity and specificity for detection of shockable rhythms in children. Cardiopulmonary resuscitation (CPR) and the early use of AEDs by first responders in the field are encouraged; AEDs may be used in the hospital setting if more advanced equipment and staff are not readily available.[52] The use of AEDs is now acceptable in all age ranges, including infants and children. Pediatric pads (attenuating pads) should be used whenever possible for children 1 year to 8 years old (or less than 25 kg).[53-56] In infants younger than 1 year, manual defibrillation is preferred.[52] If a manual defibrillator is unavailable or its use is delayed, an AED with a pediatric attenuator may be used; if neither is available, an AED without a dose attenuator may be used.[52]

The treatment algorithm and medication dosages for ventricular fibrillation and pulseless ventricular tachycardia are listed in Box 171-13. On the basis of the 2010 PALS guidelines, ventricular fibrillation and pulseless ventricular tachycardia are treated with a single defibrillation, followed immediately by 2 minutes of uninterrupted CPR.[44] Although a single shock with a biphasic defibrillator has a high likelihood of terminating ventricular fibrillation, the resulting rhythm is typically a nonperfusing rhythm, which therefore requires CPR to maintain perfusion to the heart and brain until normal cardiac contractility can resume.[44,56] Epinephrine is given with the second defibrillation, and antiarrhythmic agents are added to the treatment algorithm with the third defibrillation. Although biphasic defibrillators can convert ventricular fibrillation at lower dosages than with the previous monophasic defibrillators in adults, until more data are gathered on biphasic defibrillation dosages in children, the current AHA recommendation for pediatric defibrillation with biphasic defibrillators remains the same as that with monophasic defibrillators (i.e., starting at 2 joules/kg, followed by 4 joules/kg). The 2010 PALS guidelines recommend escalating doses for subsequent shocks, up to 10 joules/kg or the maximum adult dose delivered from the defibrillator.

Asystole and Pulseless Electrical Activity. Asystole is the most common rhythm found in cases of out-of-hospital cardiac arrest in children and is associated with a less than 1% chance of survival.[57-62] The treatment algorithm and medication dosages for asystole and pulseless electrical activity are listed in Box 171-13. Pulseless electrical activity can be a slow or fast rhythm and have a narrow or wide QRS complex. The use of high-dose epinephrine is no longer recommended.[44,52]

The key to survival from any pulseless electrical activity rhythm is to rapidly identify and to correct the underlying cause. The causes of pulseless electrical activity can be remembered by the six *h*'s and five *t*'s: hypovolemia, hypoxia, hydrogen ion (acidosis),

www.ketabpezeshki.com 66485457-66963820

hypokalemia/hyperkalemia, hypoglycemia, hypothermia, toxins, tamponade, tension pneumothorax, thrombosis, and trauma.[38,44] The most common cause of pulseless electrical activity in children is profound hypovolemia. Therefore, an intravenous fluid bolus should always be considered as a therapeutic option during the treatment of pulseless electrical activity.

Special Resuscitation Situations in Children

Children with single-ventricle physiology (e.g., hypoplastic left heart syndrome, double-outlet right ventricle physiology, among others) after a palliative shunting procedure should be given standard resuscitation care.[52] Heparin may be used in the pre-arrest or arrest of infants with a systemic–to–pulmonary artery shunt or right ventricle–to–pulmonary artery shunt to halt thrombus propagation in this low circulatory flow state.[52] A target oxyhemoglobin saturation (Spo_2) of approximately 80% is preferred in these children. End-tidal carbon dioxide readings after resuscitation may lag behind because of varying pulmonary blood flow changes that do not necessarily reflect cardiac output. The goal is to provide adequate preload with judicious fluids to balance systemic and pulmonary blood flow.[52] If it is available, extracorporeal membrane oxygenation may be considered in these patients.[52,53]

Children with a history of pulmonary hypertension should also receive standard PALS care. Preload should be optimized with isotonic saline boluses. Inhaled nitric oxide in the intensive care unit may be given to reduce PVR.[52,54] Intravenous prostacyclin is also used to decrease PVR and may be an option in the emergency department. Early contact with the child's cardiologist and cardiothoracic surgeon is instrumental in the postresuscitative care of children with CHD.

Bacterial Endocarditis

Perspective

Bacterial endocarditis involves an infection of the endothelial surfaces of the heart with a propensity for the valves. The incidence of bacterial endocarditis in children may be increasing slightly because of the many advances in surgical technology that are now allowing many children with very complex congenital heart lesions to survive. Children with indwelling intravenous lines with or without underlying CHD are also at risk for development of bacterial endocarditis. Although bacterial endocarditis most commonly occurs in children with an underlying CHD or an acquired cardiac lesion (e.g., acute rheumatic valvular heart disease), it can also occur in patients with no underlying anatomic defects of the valves or endocardium.[63]

Factors that predispose children with underlying anatomic cardiac defects to bacterial endocarditis include dental procedures and other surgical procedures involving the respiratory, gastrointestinal, or genitourinary tracts. Those cardiac lesions with a more turbulent blood flow or a higher flow velocity are more prone to development of bacterial endocarditis secondary to a greater risk of endothelial surface damage, which then increases the risk of platelet deposition and vegetation formation. Cardiac lesions that carry this higher risk include ventricular septal defects, aortic valvular stenosis, tetralogy of Fallot, single-ventricle states, prosthetic valves, and postoperative systemic-to-pulmonary shunts. Isolated secundum atrial septal defects carry a much lower risk for bacterial endocarditis because the shunt flow through the atrial septal defect is typically of a much lower velocity.

Clinical Features and Diagnostic Strategies

The early clinical manifestations of bacterial endocarditis may be nonspecific. The child may simply present with only fever and tachycardia. However, bacterial endocarditis should be suspected in any child with an anatomic cardiac defect who presents with an unexplained fever. This diagnosis should always be considered in any child with a known CHD or an acquired cardiac lesion who presents with any of the conditions listed in Box 171-14. A new heart murmur is present in less than 50% of the bacterial endocarditis cases.[64] The largest study of pediatric infective endocarditis to date[65] found common presenting signs to be fever (99%), petechiae (21%), changing murmur (21%), dental caries (14%), and hepatosplenomegaly (14%); less common signs were CHF (9%), splinter hemorrhages (5%), Roth's spots (5%), and Osler's nodes (4%).

Box 171-15 Cardiac Conditions for Which Endocarditis Prophylaxis Is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous infective endocarditis
- Congenital heart disease (CHD)*
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device during the first 6 months after the procedure†
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or device (which inhibit endothelialization)
- Cardiac transplantation recipients who have cardiac valvulopathy

From American Heart Association: Prevention of infective endocarditis. Guidelines from the American Heart Association. Circulation 116:1736, 2007.
*Except for those conditions above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

In addition to vigilance for the diagnosis of infective endocarditis, especially in children with CHD, the emergency physician should be aware of the indications for prophylaxis. In 2007 the AHA in conjunction with the American Academy of Pediatrics and the Infectious Diseases Society of America published revised guidelines for the prevention of infective endocarditis.[66] The changes simplify and greatly narrow the recommendations to provide prophylaxis for only the higher risk patients and procedures (Box 171-15). For those children for whom prophylaxis is recommended, the indications are (1) all dental procedures and (2) any manipulation or perforation of the gingival or oral mucosa.[66] Antibiotic prophylaxis for infective endocarditis is no longer recommended for gastrointestinal and genitourinary procedures (Box 171-16). The committee found that it is still reasonable to give prophylaxis for procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients (Table 171-9).[66]

Diagnostic studies for a child with suspected bacterial endocarditis include a complete blood cell count, C-reactive protein (CRP) assessment, measurement of erythrocyte sedimentation rate (ESR), three blood cultures,[67] chest radiography, and electrocardiography. Cultures from scrapings of cutaneous emboli can also aid in the diagnosis. Although the definitive diagnostic study is the echocardiogram, it is only 80% sensitive in detecting the nidus of infection on the endocardium or valves.[68] *Streptococcus viridans* and *Staphylococcus aureus* are the two most common offending organisms recovered from the blood cultures of children with bacterial endocarditis. Studies have shown that in children with CHD, 60% of the cases caused by staphylococcal species are methicillin resistant and associated with increased risk of mortality.[69]

Box 171-16 Procedures for Which Endocarditis Prophylaxis Is Recommended

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa*
Consider prophylaxis for incisional procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients

From American Heart Association: Prevention of infective endocarditis. Guidelines from the American Heart Association. Circulation 116:1736, 2007.
*The following procedures do not need prophylaxis: routine anesthetic injections through noninfected tissue, dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa.

Table 171-9 Regimens for Prophylaxis of Infective Endocarditis

		SINGLE DOSE 30-60 MINUTES BEFORE PROCEDURE	
SITUATION	AGENT	Adults	Children
Oral	Amoxicillin	2 g PO	50 mg/kg PO
Unable to take oral medications	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin	2 g PO	50 mg/kg PO
	or Clindamycin	600 mg PO	20 mg/kg PO
	or Azithromycin or clarithromycin	500 mg PO	15 mg/kg PO
Allergic to penicillins or ampicillin—unable to take oral medications	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
	or Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

Modified from American Heart Association: Prevention of infective endocarditis. Guidelines from the American Heart Association. Circulation 116:1736, 2007.

Management

Antibiotics should be started immediately after blood culture samples have been obtained. Although the choice of intravenous antibiotics depends on the suspected source of seeding and the child's immune status, a common recommended regimen includes an aminoglycoside plus a penicillinase-resistant penicillin such as oxacillin. If methicillin-resistant staphylococci are suspected, vancomycin should also be included in the initial empirical antibiotic regimen.[70]

A surge of antibiotic resistance to the three major causes of bacterial endocarditis—streptococci, staphylococci, and enterococci—has increased the mortality rate of bacterial endocarditis, now at 25 to 40%.[71] Complications of bacterial endocarditis include systemic septic emboli, pulmonary emboli, central nervous system emboli with resultant neurologic deficits, dysrhythmias, CHF, myocarditis, myocardial abscesses, and valvular obstruction and destruction. Despite appropriate antibiotic treatment, surgical intervention to remove septic vegetations or valve replacement is sometimes necessary.

Myocarditis

Perspective

Myocarditis is an inflammatory condition of the myocardium with various infectious and noninfectious origins. In the United States, the most common cause is viral; Coxsackievirus B and enteroviruses account for the majority of cases. Other viral causes include echoviruses, influenza A and B viruses, adenovirus, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, and hepatitis B virus. Bacterial causes include *Corynebacterium diphtheriae, Streptococcus pyogenes, S. aureus, Mycoplasma pneumoniae, Borrelia burgdorferi*, and meningococcus. Noninfectious causes include Kawasaki disease, acute rheumatic fever (ARF), collagen vascular disorders (e.g., systemic lupus erythematosus), toxins (e.g., cocaine and doxorubicin), endocrine disorders (e.g., hyperthyroidism), and drug-induced hypersensitivity (e.g., penicillins, sulfonamides, phenytoin, carbamazepine).

Clinical Features

Myocarditis usually has a gradual onset with preceding upper respiratory tract infection symptoms. The presenting signs and symptoms of a child with myocarditis depend on the cause of the myocarditis, the age of the patient, and the degree of myocardial inflammation. The key to diagnosis of myocarditis in infants and children is to include it in the differential diagnosis of a child with symptoms disparate from the presentation. In mild cases, the only sign of myocarditis may be tachycardia. Tachycardia that is disproportionate to the degree of fever should alert the clinician to the possibility of myocarditis.[72] Other presenting signs and symptoms include fever, myalgias, fatigue, tachypnea, wheezing, abdominal pain, and chest pain. More severe cases of myocarditis can even have signs and symptoms of acute CHF and various dysrhythmias. The physical examination may reveal a new murmur, a gallop rhythm, or a pericardial friction rub with muffled heart tones (if the myocarditis is also accompanied by pericarditis and subsequent pericardial effusion). In general, these are sick children with vague symptoms.

Diagnostic Strategies and Management

The evaluation and management of the child with myocarditis depend on the suspected cause and the presenting signs and symptoms. Blood cultures and viral titers should be considered in infectious and postinfectious cases. Appropriate antibiotics should be initiated immediately in cases with suspected bacterial origin. The chest radiograph may be normal in very mild cases, but cardiomegaly will be evident in more advanced cases. The electrocardiographic findings are usually nonspecific and can include low-voltage, nonspecific ST segment abnormalities, T wave inversions, atrioventricular blocks, and various other dysrhythmias. Creatine kinase-MB, cTnT, cTnI, CRP, and ESR may be elevated.

The echocardiogram is an essential component of the workup of any child with suspected myocarditis. The echocardiogram will not only be useful to assess the degree of left ventricular function, but it will also be able to detect associated pericardial effusion that may accompany the myocarditis. Although an endomyocardial biopsy is rarely required, it is the definitive method to confirm the diagnosis and origin of myocarditis. If the endomyocardial biopsy is performed, it will typically demonstrate a myocardial inflammation with lymphocytic and monocytic infiltrates. The goal of treatment is to maintain adequate cardiac output and to control any associated dysrhythmias. Children who present in CHF may require inotropic support and diuretics. Digoxin and the various pressors must be used very cautiously in children with

www.ketabpezeshki.com 66485457-66963820

myocarditis because the inflamed myocardium is sensitive to the dysrhythmogenesis of these medications. The use of beta-blockers is contraindicated,[72] and the routine use of immunosuppressive agents remains controversial.[73] Although the majority of children with acute viral myocarditis make a full recovery, a few patients will progress to dilated cardiomyopathy, which is characterized by dilated ventricles and impaired systolic contractility.

Pericarditis

Perspective

Pericarditis is an inflammatory process within the pericardial sac that may not be associated with a pericardial effusion. In the majority of cases, pericarditis in children is self-limited and follows a benign clinical course. In children, there are normally about 10 to 15 mL of fluid within the pericardial sac. A sudden increase or a large amount of fluid within this pericardial sac can cause a tamponade-induced decrease in stroke volume, which will cause a diminished cardiac output and hypotension.

Although the most common causes of pericarditis include bacterial and viral infections, other causes are ARF, systemic lupus erythematosus, uremia, postpericardiotomy syndrome, leukemia, lymphoma, and tuberculosis. Approximately 30% of pericarditis cases are due to bacteria such as pneumococcus, *S. aureus,* meningococcus, and *Haemophilus influenzae*.[2] Approximately 30% of the purulent bacterial pericarditis cases occur in children younger than 6 years.[28] Viral causes are common, but a specific viral pathogen is recovered in only 20 to 30% of the cases.[28] Common viral causes include Coxsackieviruses, echoviruses, adenovirus, Epstein-Barr virus, and influenza viruses.

Clinical Features

The presenting signs and symptoms of pericarditis depend on the cause of the pericarditis as well as on the amount of fluid that has accumulated within the pericardial sac. Chest pain that varies with position is a common complaint with pericarditis. The chest pain that is classically associated with pericarditis is exacerbated with inspiration and the supine position but relieved when the patient sits up or leans forward. Tachycardia is also a common finding in patients with pericarditis and may be the only clue to the diagnosis. Other physical examination findings that have been associated with pericarditis include fatigue, tachypnea, neck vein distention, pulsus paradoxus, hepatomegaly, lower extremity edema, and thready distal pulses if heart failure is present. The cardiac auscultatory findings in a patient with pericarditis can include a harsh-sounding friction rub or diminished or muffled heart tones, if there is a significant amount of fluid within the pericardial sac. The pericardial friction rub, if present, is best heard when the patient sits up or leans forward. This friction rub of pericarditis can be distinguished from a pleural friction rub by having the patient hold his or her breath during auscultation. The friction rub of pericarditis will remain present during breath-holding; the pleural friction rub will no longer be heard while the patient holds the breath.

The chest radiograph in a child with pericarditis may not reveal an enlarged cardiac silhouette, depending on the amount of fluid that has accumulated within the pericardial sac. If there is a large collection of fluid within the pericardial sac, the heart shadow on the chest radiograph will resemble a "water bottle" silhouette. Approximately 50% of pericarditis cases also have an associated pleural effusion.[2]

The classic electrocardiographic findings of pericarditis include diffuse ST segment elevation and diffuse T wave inversions in all leads. The classic electrocardiographic changes associated with pericarditis evolve through four phases (Fig. 171-13). During the initial phase, there is diffuse ST segment elevation in all leads secondary to subepicardial inflammation; PR segment depression may also be seen. During the second phase, the previously elevated ST segments begin to return to isoelectric baseline, and the T wave amplitudes begin to decrease with flattening of the T waves. During the third phase, although the ST segments are now back to isoelectric baseline, the T waves are now inverted. The fourth and final phase demonstrates complete resolution of the ST segment and T wave abnormalities. Diminished electrocardiographic voltages in all leads can also occur if there is a significant amount of fluid accumulated within the pericardial sac.

The diagnostic procedure of choice in any patient with suspected pericarditis is the echocardiogram; this study will confirm both the presence and the amount of accumulated fluid within the pericardial sac. Although echocardiography cannot accurately quantify the exact amount of fluid that has accumulated within the pericardial space, the presence of an anterior and posterior fluid collection is suggestive of a large collection.

Management

The management of a child with pericarditis depends on both the suspected cause and the amount of fluid that has accumulated within the pericardial space. These children require admission for observation and analgesia with nonsteroidal anti-inflammatory drugs. Certainly those patients with fever, respiratory distress, or signs of CHF should be admitted and an echocardiogram performed emergently. An emergency pericardiocentesis will be required in those patients who have signs of acute cardiac tamponade. Any fluid that is aspirated from the pericardial space should be sent for routine cell counts, Gram's stain, and cultures. Anti-inflammatory agents and appropriate antibiotics should also be initiated on the basis of the suspected cause. Steroids are reserved for refractory cases that are not responsive to these agents and would be considered only after an infectious etiology is ruled out.[74]

Kawasaki Disease

Perspective

Kawasaki disease, originally described as mucocutaneous lymph node syndrome by Dr. Tomisaku Kawasaki in 1967, has emerged as a significant cause of acquired cardiac disease in children in the United States. An estimated 3000 to 5000 cases of Kawasaki disease are diagnosed annually in the United States. Up to 20% of untreated children have some degree of coronary artery abnormalities.[75] This febrile, exanthematous, multisystem vasculitis is seen most commonly in children younger than 5 years with a male-to-female ratio of 1.5:1. The incidence is higher in Asian children and in certain geographic locations, such as Hawaii. Although the exact cause of this vasculitis of small and medium-sized vessels remains unknown, early clinical recognition and initiation of high-dose aspirin and intravenous immune globulin (IVIG) therapies have improved the morbidity and mortality rates of Kawasaki disease in children.

Clinical Features

The key to prevention of the coronary artery complications of Kawasaki disease is first to recognize the clinical signs and symptoms of this disease. In addition to fever, the physical examination of a child with Kawasaki disease may reveal the typical findings as listed in Box 171-17 and illustrated in Figure 171-14. The classic features of Kawasaki disease may be manifested simultaneously or in series of days; a careful history and physical examination may elucidate the need for further testing. In addition, very young

www.ketabpezeshki.com 66485457-66963820

Figure 171-13. The classic electrocardiographic progression of a patient with pericarditis. First phase: diffuse ST segment elevation. Second phase: ST segments back to isoelectric, but decreased T wave amplitude. Third phase: T wave inversion. Fourth phase: complete resolution. Notice that the first three phases of the electrocardiographic abnormalities of pericarditis in this patient are evident during the first 2 weeks of his illness. A follow-up electrocardiogram obtained 5 months later reveals a complete resolution of all the previous electrocardiographic abnormalities.

Box 171-17 Diagnostic Criteria for Kawasaki Disease

- Fever ≥5 days
- At least four of the five following physical examination findings:
  - Bilateral, nonexudative bulbar conjunctival injection (bilateral scleral injection with perilimbic sparing)
  - Oropharyngeal mucous membrane changes (pharyngeal erythema, red and cracked lips, and a strawberry tongue)
  - Cervical lymphadenopathy (with at least one node > 1.5 cm in diameter)
  - Peripheral extremity changes (diffuse erythema and swelling of the hands and feet during the acute phase or periungual desquamation during the convalescent phase of the illness). This diffuse palmar erythema seen in Kawasaki disease is in contrast to the discrete macular lesions of various viral illnesses (e.g., measles) that can sometimes be seen on the palms and soles.
  - A polymorphous generalized rash (nonvesicular and nonbullous). There is no specific rash that is pathognomonic for Kawasaki disease.

In a child with ≥4 criteria, the diagnosis may be made on day 4 of the fever.[71]

children may not have a classic presentation and require further investigation. All children with suspected Kawasaki disease, with either classic or incomplete features, should undergo echocardiography for detection of the presence and degree of coronary aneurysm.[76]

Incomplete Kawasaki Disease.

The classic presentation of Kawasaki disease is a clinical diagnosis of four or more of the five criteria in a child who is febrile 5 days or more. However, these strict criteria may miss a substantial number of children who present with incomplete Kawasaki disease. Any child may have an incomplete presentation, but this is mostly seen in infants younger than 6 months.[76]

The AHA's Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease has published consensus guidelines on the approach to incomplete Kawasaki disease.[71] The more inclusive criteria recommend that in a child who is febrile 5 days or more, the presence of two or three criteria should prompt further testing. A CRP of 3 mg/dL or more or an ESR of 40 mm/hr or more or both necessitate further laboratory investigations, such as those listed in Box 171-18. All of these children will also need

www.ketabpezeshki.com 66485457-66963820

Figure 171-14. Classic physical examination findings of Kawasaki disease. Note the bilateral nonexudative scleral injections (A) with perilimbic sparing (the thin margin of white sclera around the cornea), red and cracked lips with a strawberry tongue (B), diffuse palmar erythema (C), red soles (D), and polymorphous exanthem (E). The diffuse palmar erythema of Kawasaki disease (C) is distinct from the palmar findings seen in other viral illnesses, such as the discrete macular lesions on the palms in this child with measles (F).

echocardiography to assess for coronary aneurysm, and the recommendation is to treat empirically those whose supplementary laboratory values (see Box 171-18) are positive for systemic inflammation while echocardiographic confirmation is awaited.[76]

Children with a CRP of less than 3 mg/dL and an ESR of less than 40 mm/hr may be observed daily and reassessed. The committee also added a stipulation that the infant 6 months or younger with fever of 7 days or more should also undergo supplemental laboratory testing and, if any signs of systemic inflammation are found, should have an echocardiogram. This underscores the current limits of diagnosis of Kawasaki disease as well as the obligation to prevent the disastrous sequelae of aneurysmal development.

Differential Considerations

Measles can mimic Kawasaki disease but is rare in vaccinated children (i.e., a febrile illness with red eyes, a rash, and erythema of the oropharynx). The measles rash classically begins on the head and face and progresses caudally. The rash of Kawasaki

Box 171-18 Supplemental Laboratory Criteria for Kawasaki Disease

Albumin ≤3 g/dL
Anemia for age
Platelet count of ≥450,000/mm^3
White blood cell (WBC) count ≥15,000 mm^3
Elevation of alanine aminotransferase
Sterile pyuria of ≥10 WBCs per high-power field

From Newburger JW, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: A statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. Circulation 110:2747, 2004.

disease typically begins on the trunk and then spreads to the face and extremities. In contrast, Kawasaki disease can exhibit a polymorphous rash that is nonbullous and nonvesicular.

The palmar lesions of measles are discrete macular lesions (Fig. 171-14F), whereas the palmar finding in children with Kawasaki disease is diffuse erythema, which may later lead to desquamation (Fig. 171-14C).

Streptococcal disease, including pharyngitis and scarlet fever, can be confused with Kawasaki disease, but conjunctivitis and swelling of the hands and feet are unusual for streptococcal disease. Other infectious or autoimmune causes that may mimic Kawasaki disease include Rocky Mountain spotted fever, leptospirosis, Stevens-Johnson syndrome, and juvenile rheumatoid arthritis.[76]

There are many imitators of Kawasaki disease. Conversely, this systemic vasculitis can affect any organ system and thus mislead the clinician in diagnosis. For example, Kawasaki disease can be manifested with nausea, vomiting, and abdominal pain in a febrile child, which may be mistaken for a surgical abdomen. In addition, a febrile, irritable child with Kawasaki disease may exhibit a cerebrospinal fluid pleocytosis and be misdiagnosed with viral meningitis. For this reason, Kawasaki disease should be included in the differential diagnosis of any child with several days of fever, rash, and nonpurulent conjunctivitis to avoid the pitfall of early diagnostic closure.

Clinical Course

Kawasaki disease is postulated to be caused by an infectious agent that enters the respiratory tract and initiates an oligoclonal immunoglobulin A response, which activates lymphocytes, cytokines, and proteinases that weaken vessel walls and predispose the entire circulation to aneurysms.[77] The main reason to recognize this disease entity in children is to initiate prompt therapies to prevent the cardiac complications of Kawasaki disease, which occur in two phases. Approximately 25% of patients have mild diffuse myocardial inflammation. This occurs during the acute febrile period and is characterized by tachycardia, a gallop rhythm, and nonspecific ST-T wave changes. Up to 5% of the children also exhibit some degree of CHF during this acute phase of their illness. This carditis usually resolves when the fever resolves. Pericardial effusions also occur in up to 20 to 40% of cases. Mild mitral and aortic regurgitation is also seen in 1 to 2% of untreated cases on echocardiographic examinations. This phase of the disease is mild and self-resolving. Therapy during this phase of the illness is primarily supportive.

The second phase of the disease involves coronary artery dilation, which usually peaks 2 to 4 weeks from the onset of the illness and is seen in 15 to 25% of the untreated patients with Kawasaki disease.[78] Without the appropriate treatment, 15 to 20% of children with Kawasaki disease go on to have coronary aneurysms within 1 to 3 weeks from the onset of their illness.[2] These coronary aneurysms can then lead to myocardial infarction, thrombosis, rupture, and a variety of ischemia-induced dysrhythmias. Significant risk factors for coronary aneurysmal formation include male gender, age younger than 1 year or older than 8 years, prolonged febrile period longer than 10 to 14 days, early myocarditis, anemia (hemoglobin <10 g/dL), white blood cell count greater than 30,000, increased band count, elevated ESR, elevated CRP level, low serum albumin levels, aneurysms involving other arteries (renal, axillary, or iliac), and giant coronary aneurysms (>8 mm in diameter). Death from Kawasaki disease is primarily due to myocardial infarction secondary to coronary artery occlusion. Giant coronary artery aneurysmal rupture is rare. Although most of the fatalities of Kawasaki disease occur within 6 weeks from the onset of the illness, sudden death can also occur many years after the illness. Prompt recognition and treatment have decreased this mortality rate from 2% to less than 0.01%.[75]

Management

The main goal of treatment during the acute febrile phase of Kawasaki disease is to provide supportive care and to decrease the inflammation of the myocardium and coronary arteries. The two major components of treatment include IVIG infusion and high-dose aspirin therapy, which together have an additive effect. This combination of IVIG and high-dose aspirin, when it is initiated within 10 days from the onset of the illness, can substantially decrease the progression to coronary artery dilation and aneurysm formation compared with aspirin therapy alone and results in a more rapid resolution of fever and the other indicators of acute inflammation.[76] However, despite prompt treatment with IVIG and high-dose aspirin, 2 to 4% of the children still have coronary artery abnormalities.[76]

The current IVIG regimen involves an infusion of 2 g/kg during 10 to 12 hours. Side effects of IVIG include hypotension, nausea, vomiting, headache, and seizures. Close cardiac monitoring during the IVIG infusion is recommended. The 5 to 10% of children who receive IVIG and experience a persistent or recurrent fever after the initial dose of IVIG may be given a second infusion at the same dose. Approximately two thirds of those children who fail to respond to the initial dose of IVIG will improve with the second infusion.

Aspirin is initiated at 80 to 100 mg/kg/day orally divided into an every-6-hour dosing regimen until the child is afebrile for 48 to 72 hours (or longer). This dose is then decreased to 3 to 5 mg/kg orally each day until the laboratory study results return to normal, which typically occurs 6 to 8 weeks after the onset of the disease. Aspirin therapy is continued beyond this period only in those children in whom coronary artery abnormalities are present. Ibuprofen can antagonize the antiplatelet effects of aspirin and should be avoided during treatment.[76]

The use of corticosteroids as primary treatment has not been well established. A multicenter, randomized, double-blind study to determine the efficacy of the addition of methylprednisolone to initial conventional therapy showed no difference in clinical outcome, including dimensions of coronary artery aneurysms, length of hospital stay, and rate of re-treatment with IVIG.[79] The current recommendations include corticosteroids for refractory cases of Kawasaki disease, in which high-dose aspirin is continued, a second dose of IVIG is administered, and corticosteroids are added to decrease the risk of coronary artery aneurysm.[76,80] Other complications, such as coronary aneurysmal thrombosis, likewise have limited data to guide management. Therapeutic options include streptokinase, tissue-type plasminogen activator, and interventional cardiac catheterization.[76]

The follow-up of children with Kawasaki disease depends on the degree and presence of carditis and coronary artery abnormalities detected on the initial echocardiogram. Other imaging modalities used to follow aneurysmal parameters include

www.ketabpezeshki.com 66485457-66963820

electron-beam computed tomography, coronary magnetic resonance angiography, and multislice spiral computed tomography.[76] Those children with more severe cardiac abnormalities require close follow-up by a cardiologist who is experienced in managing the cardiac complications of Kawasaki disease. Overall, prompt diagnosis and appropriate therapies can prevent coronary aneurysm formation in up to 95% of the cases as well as result in rapid symptomatic improvement in up to 90% of the cases.[81]

Acute Rheumatic Fever

Perspective

ARF is the result of a delayed immune reaction to a group A streptococcal infection. ARF is one of the most common causes of acquired heart disease in children. In the United States, ARF most commonly occurs in children 5 to 15 years of age and has an attack rate of 0.3% in children with an untreated streptococcal infection. Although this disease affects multiple organ systems, carditis is the most serious complication.

Clinical Features and Diagnostic Considerations

The diagnosis of ARF is based on the Jones criteria (Box 171-19). In addition to the Jones criteria, there must also be evidence of an antecedent streptococcal infection, which can be documented by a positive throat culture, a positive rapid streptococcal antigen test finding, or an elevated antistreptolysin O (ASO) titer. The ASO titer begins to rise 1 to 3 weeks after streptococcal infection, peaks at 3 to 5 weeks, and reliably falls to baseline after 6 months.[82] The streptozyme test is not as reliable and therefore should not be used as a definitive test for evidence of an antecedent group A streptococcal infection.[83] The diagnosis of ARF is made in a patient with a documented antecedent streptococcal infection who exhibits either two major criteria or one major plus two minor criteria. The most common presenting major criterion is the migratory polyarthritis, which commonly involves the larger joints of the extremities as well as the smaller tarsal joints in the foot and the smaller carpal joints in the hand. The carditis of ARF most commonly involves valvulitis of the mitral and aortic valves, which clinically is manifested as occult mitral or aortic insufficiency. The murmur of mitral insufficiency is characterized as a holosystolic murmur best heard over the apex with radiation to the axilla. The murmur of aortic insufficiency is characterized as a diastolic murmur that is best heard over the base of the heart. Innocent murmurs that are normally exacerbated with fever can be mistaken for the murmurs of mitral or aortic insufficiency. The other cardiac manifestations of ARF include CHF, pericarditis, and various degrees of heart block. The two dermatologic major criteria (erythema marginatum and subcutaneous nodules) and chorea occur less commonly than the migratory polyarthritis and carditis. Chorea may occur as the only manifestation of ARF. If arthritis is used as a major component, arthralgia cannot be used as a minor component to make the diagnosis. Likewise, if carditis is used as a major component, a prolonged PR interval cannot be used as a minor component.[83]

In addition to the ECG, CRP level, ESR, and documentation of an antecedent streptococcal infection, the diagnostic workup of ARF should also include a chest radiograph as well as an echocardiogram to evaluate the degree of cardiac involvement.

Box 171-19 Jones Criteria for the Diagnosis of Acute Rheumatic Fever

The diagnosis of acute rheumatic fever is based on the documentation of an antecedent streptococcal infection and either two major criteria or one major criterion plus two minor criteria.

Major Criteria
- Carditis
- Migratory polyarthritis
- Erythema marginatum
- Subcutaneous nodules
- Chorea

Minor Criteria
- Clinical findings
  - Fever
  - Arthralgia
- Laboratory findings
  - Elevated C-reactive protein or erythrocyte sedimentation rate
  - Prolonged PR interval
- Supporting evidence of an antecedent group A streptococcal infection with either
  - A positive throat culture or rapid streptococcal antigen test result
  - An elevated antistreptolysin O titer

Differential Considerations

The differential diagnosis of ARF includes myocarditis, bacterial endocarditis, Lyme disease, systemic lupus erythematosus, juvenile rheumatoid arthritis, serum sickness, and septic arthritis.

Management

The acute management of ARF should first focus on stabilization and treatment of any of the symptomatic cardiac manifestations of the illness, such as CHF or tamponade due to a pericardial effusion. Additional goals in ARF management include appropriate antibiotic therapy to eradicate the streptococcal infection, bed rest, and anti-inflammatory agents for the arthritis. Steroids should be used in the treatment of carditis only under direction of a cardiologist. Another important aspect in the management of ARF is the prevention of recurrent attacks through the prophylactic use of penicillin, which can be given as monthly injections of 1.2 million units of benzathine penicillin G. Alternative prophylactic regimens include oral penicillin administered twice daily and, for penicillin-allergic patients, twice daily oral erythromycin. This prophylaxis with penicillin or erythromycin is required until 18 years of age at the minimum but can be continued for life, depending on the degree of cardiac involvement and the risk for recurrence.

Cardiac Causes of Sudden Death in Young Athletes

Perspective

In a large registry study of 1866 sudden deaths in young athletes, 1048 (56%) were found to be due to cardiovascular disease, and 416 (22%) were due to direct blunt trauma.[84] The most common cardiovascular cause of sudden death in the athlete is hypertrophic cardiomyopathy, which accounts for up to 36% of the cardiovascular-related cases (Box 171-20).[70]

Specific Disorders

Congenital Coronary Artery Anomalies. An additional 24% of the cases of sudden death are due to various anomalies of the coronary arteries.[85] Congenital coronary artery anomalies are difficult to detect from a clinical standpoint, but 37% of those individuals who died of congenital coronary artery anomalies exhibited previous symptoms of exercise-induced syncope or chest pain.[86] The

Box 171-20 Cardiovascular Causes of Sudden Death in Young Athletes

Hypertrophic cardiomyopathy
Various congenital coronary artery anomalies
Prolonged QT interval syndrome
Various preexcitation syndromes (e.g., Wolff-Parkinson-White syndrome)
Commotio cordis
Aortic rupture secondary to Marfan syndrome
Idiopathic dilated cardiomyopathy
Myocarditis
Coronary artery disease secondary to Kawasaki disease
Aortic stenosis
Mitral valve prolapse

exact pathophysiologic mechanism of sudden death in individuals with congenital coronary anomalies is unknown. Although there are a variety of congenital coronary artery anomalies, the most common potentially lethal lesion is the anomalous left coronary artery, in which the left main and right coronary arteries both arise from the right sinus of Valsalva. Individuals with this particular anomaly have a 46% incidence of sudden death, with more than 85% of the known cases of sudden death occurring during exercise.[84] Congenital coronary artery hypoplasia is another uncommon cause of exercise-induced sudden death. Any athlete with exertional syncope or chest pain should be evaluated by a cardiologist for the possibility of a congenital coronary artery anomaly. If an anomaly is detected and surgically corrected, the athlete may resume full activity and participation in competitive sports.

Marfan Syndrome. Individuals with Marfan syndrome should be evaluated for potential cardiac abnormalities before being allowed to participate in competitive sports. Clinical manifestations of the disease include tall and slender habitus, striae atrophicae of the skin (multiple stretch marks on skin), disproportionately long extremities compared with the trunk, scoliosis, pectus excavatum or carinatum, and dislocated lenses of the eye. Approximately 50% of patients with Marfan syndrome have cardiac manifestations, such as mitral valve prolapse or aortic dilation. The most serious cardiac complication of Marfan syndrome is the progressive dilation of the aorta with the potential risk of aortic rupture, which most commonly involves the descending portion of the aorta. Therefore, patients with Marfan syndrome should be prohibited from participation in contact sports. Those individuals who are known to have aortic dilation should also be prohibited from participation in any competitive sports regardless of the degree of contact involved.[85] All patients with Marfan syndrome with or without cardiac involvement on their initial evaluation should be observed by a cardiologist with serial imaging studies of the aorta by echocardiography, magnetic resonance imaging, or computed tomography.

Hypertrophic Cardiomyopathy

Perspective. Although the nonobstructive form of hypertrophic cardiomyopathy is an uncommon cardiac malformation that occurs in only 0.2% of the general population, it is the single most common cardiac cause of sudden death in the young athlete.[87-89] Hypertrophic cardiomyopathy is a familial disease that is inherited in an autosomal dominant fashion with variable penetrance. The hypertrophy of the left ventricle in this condition is idiopathic in nature and not due to chronic pressure overload conditions, such as systemic hypertension or aortic stenosis. The systolic left ventricular contractile function is vigorous but the thickened muscle of the left ventricle is stiff, resulting in impaired ventricular relaxation and high diastolic filling pressures.[90]

Sudden death in previously asymptomatic individuals with hypertrophic cardiomyopathy occurs during moderate or severe physical exertion. The proposed pathophysiologic mechanism of sudden death during exertion in these individuals is thought to be a transient decrease of blood flow out through the aorta or dysrhythmia secondary to the hypertrophied ventricular myocardium.

Clinical Features. Some individuals with hypertrophic cardiomyopathy have experienced previous "warning" episodes of chest pain, dyspnea, syncope, or palpitations during vigorous activities. A family history of sudden unexplained death in young adults should also alert the clinician to the possibility of hypertrophic cardiomyopathy. The majority of young athletes who die of this condition have the nonobstructive form of hypertrophic cardiomyopathy, and the classic loud systolic ejection murmur that is present with the obstructive form may not be heard during the routine pre-sports physical examination.[91]

If a systolic murmur along the lower left sternal border is heard on the routine screening physical examination of a young athlete, a Valsalva maneuver may help differentiate the murmur of aortic stenosis from the systolic murmur associated with the obstructive form of hypertrophic cardiomyopathy. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. The transient reduction in the size of the left ventricle will increase the degree of obstruction and thus cause an increase in the intensity of the systolic murmur heard with the obstructive form of hypertrophic cardiomyopathy. In contrast to this, the systolic murmur of aortic stenosis will decrease in intensity during a Valsalva maneuver because of the transient reduction of blood flow through the stenotic aortic valve.

Current recommendations for pre-sports screening include a detailed family and personal history of known or suspected heart disease, physical examination, and 12-lead ECG. If any suspicion remains, further workup (e.g., echocardiography, Holter monitoring, other imaging studies) and referral to a cardiologist are indicated.[91]

Diagnostic Studies. The electrocardiographic findings in individuals with hypertrophic cardiomyopathy typically reveal various degrees of left ventricular hypertrophy and left atrial enlargement. Other electrocardiographic findings include prominent Q waves in the inferolateral leads and diffuse T wave inversions. The most accurate study for the diagnosis of hypertrophic cardiomyopathy is the echocardiogram, which will demonstrate various degrees of left ventricular hypertrophy most commonly involving the ventricular septum in up to 90% of the cases.[90] Those patients who have echocardiographic evidence of hypertrophic cardiomyopathy should be observed with serial echocardiographic examinations to monitor progression of the condition.

Management. Although beta-blockers have been used in patients with hypertrophic cardiomyopathy, they have not been shown to prevent sudden death in these patients. The use of digoxin is contraindicated in patients with hypertrophic cardiomyopathy because its positive inotropic effect may worsen the left ventricular outflow obstruction. Sudden death in these patients with hypertrophic cardiomyopathy is thought to be due to exertion-induced ventricular fibrillation or pulseless ventricular tachycardia. Therefore, the current recommendation is that all individuals who are diagnosed with hypertrophic cardiomyopathy as well as those individuals with an equivocal diagnosis of hypertrophic cardiomyopathy should not participate in vigorous activities and competitive sports.

Prolonged QT Syndrome

Perspective. In 1957, Jervell and Lange-Nielsen first described the association of recurrent syncope, sudden death, and long QT interval in a series of deaf patients. Later, in 1963, Romano reported a similar association of symptoms with long QT intervals in patients with normal hearing. Both the Jervell–Lange-Nielsen and the Romano-Ward syndromes are inherited disorders with

www.ketabpezeshki.com 66485457-66963820

variable penetrance, characterized by a prolonged QT interval that has been associated with sudden death. The corrected QT interval (QTc) in normal individuals should not exceed 0.44 second in children or 0.42 second in adolescents. Individuals with QTc intervals longer than 0.55 second have a higher risk of sudden death. Prolongation of the QT interval predisposes the individual to ventricular tachycardia, torsades de pointes, and ventricular fibrillation, which is often initiated by a premature ventricular contraction occurring during the prolonged repolarization phase. In addition to the inherited syndromes of prolonged QT intervals, other causes of prolonged QT intervals include hypocalcemia, hypokalemia, hypomagnesemia, myocarditis, and medications (e.g., procainamide, erythromycin, cyclic antidepressants, phenothiazines, quinidine, organophosphates).

Clinical Features. Symptoms in the young athlete that are suggestive of QT prolongation include exercise-induced palpitations, chest pains, syncope, dizziness, and atypical seizures. The young athlete who has any of these symptoms should be evaluated by a cardiologist, especially if the family history is positive for sudden unexplained death, cardiac problems, syncope, or deafness. Any young athlete who has been diagnosed with a prolonged QT syndrome should be prohibited from participation in competitive sports and vigorous activities. The growing popularity and presence of AEDs in public places and at sporting events can potentially save the lives of those athletes who suddenly collapse because of an underlying prolonged QT syndrome–induced nonperfusing ventricular dysrhythmia.

Management. Treatment of a prolonged QT interval depends on the cause. Correction of any underlying metabolic disorder and discontinuation of a medication that induced the prolongation of the QT interval are the easiest therapies to implement. Magnesium sulfate is the drug of choice in the treatment of torsades de pointes. Antidysrhythmic agents that also can prolong the QT interval, such as procainamide and amiodarone, should be avoided. Therefore, the safest medication to use in a patient with prolonged QT interval–induced ventricular tachycardia or fibrillation is lidocaine. Beta-blockers have been used to prevent sudden ventricular dysrhythmias in those patients with the familial forms of QT prolongation. Adjunctive treatment in these selected patients also includes the insertion of pacemakers or internal defibrillators.

Commotio Cordis. The phenomenon of commotio cordis occurs when an object such as a baseball strikes the chest and produces sudden death. This phenomenon most commonly occurs in children between 5 and 15 years of age with no known predisposing cardiac conditions.[85,92] Although commotio cordis most commonly occurs in baseball, it has also been reported to occur in ice hockey, lacrosse, softball, and fist fights.[78] In a few cases in which the cardiac rhythm was documented after the blunt trauma to the chest, the most common rhythm documented was ventricular fibrillation.[93] The majority of patients who sustain commotio cordis do not survive, especially if they are not rapidly treated with defibrillation. If an AED is not immediately available and the patient is completely unresponsive with no pulse after sustaining a direct blow to the chest, some practitioners have proposed that performance of chest thumps during CPR may be of some benefit under this particular circumstance.

KEY CONCEPTS

- The possibility of a congenital heart defect should be considered in an infant who presents with central cyanosis that does not respond to 100% supplemental oxygen (hyperoxia challenge).
- Neonates with duct-dependent cardiac lesions typically present within the first 2 to 3 weeks of life with either acute cyanosis or shock. Initiation of a PGE_1 infusion (0.05-0.1 µg/kg/min) will be lifesaving in these neonates.
- Treatment of a hypoxic tet spell first includes the placement of an infant in the knee-to-chest position or of an older child in a squatting position to increase SVR and the provision of supplemental oxygen. Sedative agents can be used to decrease hyperpnea. Various medications can be used as adjunctive treatment to increase the SVR and thereby decrease the degree of right-to-left shunting across the ventricular septal defect.
- Prompt recognition of the clinical findings and symptoms of Kawasaki disease along with the rapid initiation of high-dose aspirin and IVIG infusion can prevent the formation of coronary aneurysms.
- Acute bacterial endocarditis should always be considered in a child with a known congenital heart defect or an acquired cardiac defect who presents with fever of unknown origin, acute neurologic deficits, new-onset microscopic hematuria, myalgias, splenomegaly, petechiae, or other signs of systemic embolization.
- Oxygen, diuretics (furosemide), and inotropic agents (digoxin) are the mainstays for treatment of infants and children who present with CHF.
- If vagal maneuvers fail to convert stable paroxysmal supraventricular tachycardia in children, rapid adenosine administration (0.1 mg/kg for the first dose, followed by 0.2 mg/kg on repeated doses) is the treatment of choice. Verapamil should be avoided in children younger than 1 year because of its profound hypotensive effects.
- One should consider the use of lidocaine instead of amiodarone in cases of ventricular fibrillation or ventricular tachycardia due to medications (e.g., cyclic antidepressants) or toxins that prolong the QT interval.
- Young athletes with a positive family history of sudden unexplained death or exertion-induced symptoms such as chest pain, dyspnea, palpitations, and syncope should be evaluated by a cardiologist before their resumption of vigorous activity.
- The increased presence of AEDs in public places and at sporting events can potentially save the lives of more young athletes who suddenly collapse secondary to hypertrophic cardiomyopathy, prolonged QT syndromes, and commotio cordis.

Chapter 172

Gastrointestinal Disorders

Mark A. Hostetler

PERSPECTIVE

Gastrointestinal disorders affecting the pediatric population vary significantly with the age of the child. Consideration of age as well as of signs and symptoms has an important role in distinguishing cause. Infants, for example, may have disorders such as necrotizing enterocolitis (NEC), hypertrophic pyloric stenosis, or intussusception, whereas older children are more likely to present with appendicitis, pancreatitis, or biliary tract disease.

DISTINGUISHING PRINCIPLES OF DISEASE

Pediatric gastrointestinal disorders can be divided into different groups on the basis of their unique pathophysiologic mechanisms and reasons for development. Several disorders occur as a normal variant of development (neonatal jaundice, gastroesophageal reflux, hypertrophic pyloric stenosis), congenital malformations (malrotation, Meckel's diverticulum), or genetic abnormalities (Hirschsprung's disease). Idiopathic causes include NEC, intussusception, Henoch-Schönlein purpura (HSP), and inflammatory bowel disease (IBD).

SPECIFIC DISORDERS

Neonatal Jaundice

Perspective

Many infants become jaundiced during the newborn period, most often as a result of a benign, self-limited process. *Physiologic jaundice of the newborn,* the most common cause of neonatal jaundice, occurs in approximately 60% of normal newborns during the first week of life. *Breast milk jaundice* is the second most common cause of jaundice in the newborn period.

Principles of Disease

Bilirubin is formed by the breakdown of heme-containing proteins, primarily hemoglobin. Heme protoporphyrin is sequentially degraded into biliverdin and unconjugated bilirubin. Unconjugated bilirubin binds to albumin in the blood and is carried to the liver, where it is conjugated by glucuronyl transferase and excreted into bile. Jaundice may be caused by increased amounts of either unconjugated or conjugated bilirubin and becomes clinically apparent when the total bilirubin level reaches approximately 5 mg/dL. Conjugated hyperbilirubinemia occurs when the direct-reacting portion exceeds 2 mg/dL or is greater than 20% of the total.

The exact pathogenetic mechanism of breast milk jaundice is uncertain. Breast milk jaundice may be hormonally mediated or related to intestinal excretion and resorption of bile. Other causes of jaundice vary significantly, depending on the percentage conjugation and the age of the infant (Tables 172-1 and 172-2). Although jaundice in adults usually is the direct result of primary liver disease, infantile jaundice has a variety of extrahepatic causes—genetic, metabolic, infectious, and obstructive. The list of diagnostic possibilities in neonatal jaundice is extensive and requires careful consideration because the morbidity and mortality rates for many of these entities are high.

Clinical Features

Physiologic jaundice of the newborn is the most common cause of neonatal jaundice and occurs in normal newborns during the first week of life. Affected infants are born with normal bilirubin levels that gradually increase to a peak level of 6 mg/dL on the third day of life and then decline to normal within 2 weeks. Breast milk jaundice is the next most common cause of hyperbilirubinemia in newborns. Affected infants exhibit the same gradual increase seen with physiologic jaundice. Levels continue to increase, however, and reach a higher peak level at 10 days to 3 weeks of life. Elevated levels may persist for 3 to 10 weeks and then gradually subside.

Toxic levels of bilirubin (more than 20 mg/dL and dependent on age) may be associated with neurotoxicity, encephalopathy, and the development of kernicterus. Kernicterus is characterized by yellow staining in areas of the brain, including the basal ganglia. Clinical manifestations begin with poor feeding and lethargy and may progress to muscle rigidity, opisthotonos, seizures, and death. Survivors may have residual problems with coordination and hearing and learning disabilities.[1] The cornerstones of therapy are phototherapy and exchange transfusion.

Diagnostic Strategies

Although physiologic jaundice of the newborn and breast milk jaundice are most common, it is important to identify truly pathologic causes of jaundice. Initial testing requires determination of fractionated levels of total and direct bilirubin. Box 172-1 lists indications for workup in infants presenting with hyperbilirubinemia. Conjugated (direct) hyperbilirubinemia is always pathologic. In such cases, a minimal workup should include a complete blood count (CBC) with peripheral smear and a Coombs test for immune-mediated major blood group incompatibility. Ill-appearing infants also require finger-stick blood glucose measurement, electrolyte panel, urine assay for reducing substances, and

Box 172-1 Indications for Workup in Jaundiced Infants

Jaundice appearing within 24 hours of birth
Elevated direct (conjugated) bilirubin level
Rapidly rising total serum bilirubin unexplained by history or physical examination
Total serum bilirubin approaching exchange level or not responding to phototherapy
Jaundice persisting beyond 3 weeks of age
Sick-appearing infant

serum ammonia determination to rule out inborn errors of metabolism.[2]

Differential Considerations

Birth history should be obtained to elicit any history of trauma because large, resolving hematomas can result in jaundice. Family history should focus on identification of siblings or other relatives with a history of jaundice or genetic or metabolic disorders and any unexplained infant deaths. Tables 172-1 and 172-2 present full lists of differential considerations for jaundiced infants and children, respectively.

Infants with direct hyperbilirubinemia represent a special subset of patients. All infants with direct hyperbilirubinemia require hospital admission and evaluation for the cause of the jaundice based on history and presenting signs and symptoms. This evaluation may include any or all of the following: sepsis workup, TORCHS (toxoplasmosis, other infections, rubella, cytomegalovirus, herpes, syphilis) titers, basic metabolic studies, α_1-antitrypsin, sweat test for cystic fibrosis, ultrasound studies, radioisotope (hepatobiliary iminodiacetic acid [HIDA] or diisopropyl iminodiacetic acid [DISIDA]) scan, and liver biopsy. In children, hemolytic anemia, infection, and drugs are the most common causes of jaundice. The history should focus on travel, exposures, medications, and associated signs and symptoms, such as fever, malaise, and weight loss. Gentle palpation of the liver is

www.ketabpezeshki.com 66485457-66963820

useful to estimate size, firmness, and tenderness and to distinguish hepatomegaly from liver inflammation.

Management

Treatment of infants with hyperbilirubinemia centers on the prevention of kernicterus. Guidelines for use of phototherapy and exchange transfusion have been recommended by the American Academy of Pediatrics[3] (Fig. 172-1). Feeding should be continued to the extent possible because oral intake stimulates enterohepatic circulation and decreases bilirubin levels. Unless the infant is severely jaundiced, breast-feeding can be continued and supplemented with formula as needed. Infants who are premature or who have significant comorbidities require treatment at lower levels. Phototherapy often is now readily available on an outpatient basis.

Disposition

In general, infants with bilirubin levels greater than 18 to 20 mg/dL require hospital admission and phototherapy. All infants with direct hyperbilirubinemia require admission and workup.

Hypertrophic Pyloric Stenosis

Perspective

Hypertrophic pyloric stenosis is the most common cause of infantile gastrointestinal obstruction beyond the first month of life. This condition occurs in 1 of every 250 live births.[4] Boys are affected at four times the rate of girls. Hypertrophic pyloric stenosis tends to run in families; however, the exact pattern of inheritance is unclear. The incidence rate is 1 in 14 if the father is affected; the rate is even higher if the mother is affected.[4] Whites are affected more often than African Americans, and the disease is rare in Asian Americans.

Principles of Disease

Infants are born with a normal pylorus that undergoes hypertrophy only as time progresses. The exact etiology is unknown. As the pylorus continues to hypertrophy, there is progressive gastric outlet obstruction. As vomiting continues, the infant loses hydrogen and chloride ions through emesis of gastric juices. As this metabolic derangement worsens, the kidney attempts to retain

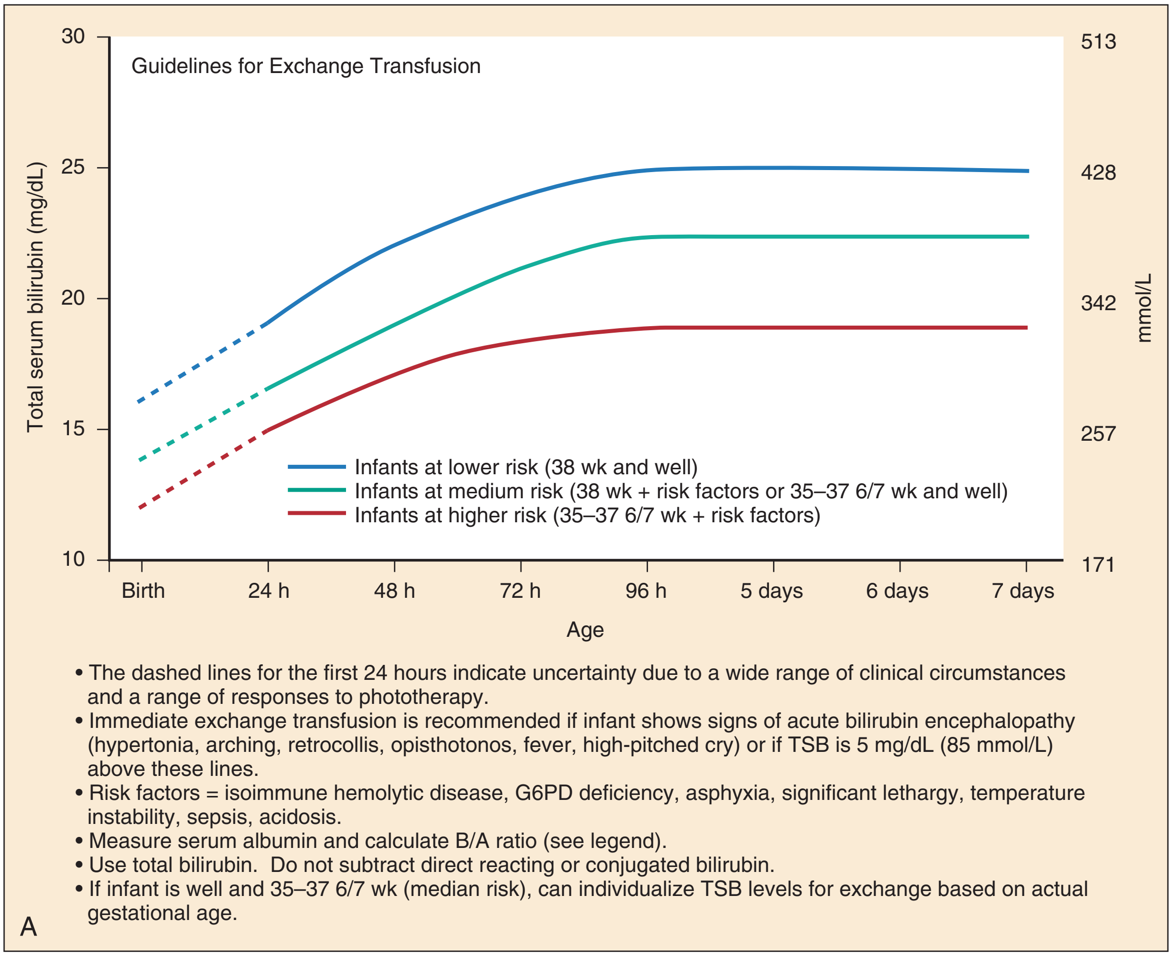

Figure 172-1. A, Guidelines for exchange transfusion in infants 35 weeks or more of gestation. Note that these suggested levels represent a consensus but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the total serum bilirubin (TSB) rises to these levels despite intensive phototherapy. For rehospitalized infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours. *B/A,* bilirubin/albumin; *G6PD,* glucose-6-phosphate dehydrogenase.

www.ketabpezeshki.com 66485457-66963820

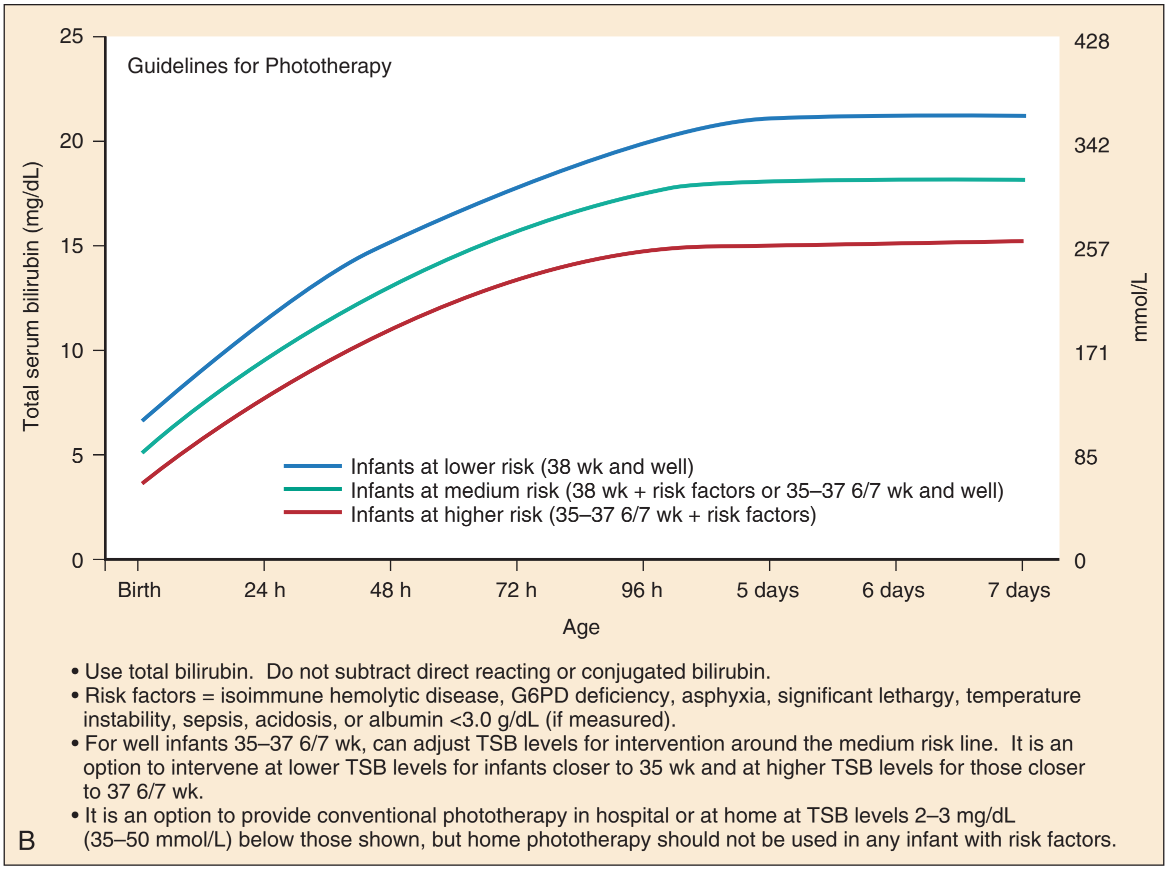

Figure 172-1, cont'd. B, Guidelines for phototherapy in hospitalized infants 35 weeks or more of gestation. Note that these guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics 114:305, 2004.)

hydrogen ions in exchange for potassium, resulting in a hypochloremic, hypokalemic metabolic alkalosis.

Clinical Features

Infants classically present at 2 to 6 weeks old with gradually progressive emesis that becomes projectile and remains nonbilious. Infants remain vigorous with a ravenous appetite. They rapidly finish an entire feeding, only to regurgitate the entire volume in a projectile fashion. In the later stages of the disease, children may exhibit visible waves of abdominal peristalsis in response to intense contractions against an obstruction. Children in the later stages of disease may exhibit marasmus (protein-calorie malnutrition) as a result of impaired nutrient absorption.

Diagnostic Strategies

Children may have a palpable pylorus, commonly referred to as an olive in the right epigastrium, on abdominal examination. Placement of a nasogastric tube and emptying the stomach or placement of the infant in the prone position often facilitates palpation. Hypertrophic pyloric stenosis may be confirmed by ultrasonography or upper gastrointestinal series. Ultrasonography is the diagnostic modality of choice because it is simple, readily available, and without serious complications such as aspiration. With both modalities, reported accuracy is greater than 95%. Ultrasound examination reveals a thickened pylorus, which is diagnostic.[5] A characteristic "string sign," reflecting passage of contrast material through the narrowed pyloric sphincter, can be seen in the upper gastrointestinal tract. In advanced stages with complete obstruction at the pylorus, plain films may reveal an enlarged body of the stomach and pylorus (Fig. 172-2).

Differential Considerations

Etiologic possibilities vary by whether the course of vomiting has been sudden in onset, gradually progressive, or chronic. The frequency and volume of emesis may have important implications about the severity of disease and the potential risk for dehydration or electrolyte disturbance. In infants, other major considerations in the differential diagnosis include gastroesophageal reflux and malrotation. The age of the child and the timing of vomiting provide important clues to the etiology. Reflux classically begins early in life, usually shortly after birth, and remains relatively constant. With pyloric stenosis, vomiting does not begin until 2 to 3 weeks of age and then becomes increasingly severe and projectile; the emesis is rarely if ever bilious. In neonates, bilious vomiting requires diagnostic evaluation to rule out the possibility of malrotation with volvulus.[6] The imaging modality of choice for pyloric stenosis is ultrasonography.

Many causes of vomiting do not have a true gastrointestinal origin, including sepsis, increased intracranial pressure, middle ear disturbances, urinary tract infections, inborn errors of metabolism, pain, medications, and drug intoxications. Differential considerations for vomiting in children vary by age (Table 172-3).

www.ketabpezeshki.com 66485457-66963820

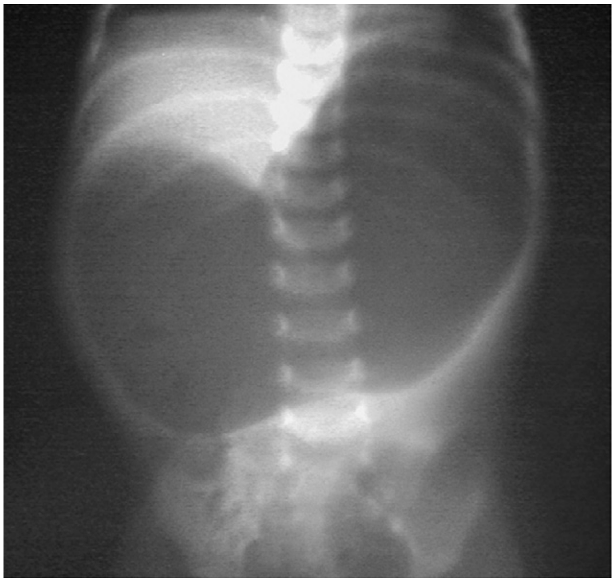

Figure 172-2. Plain radiograph of the abdomen revealing enlargement of the body and pyloric portions of the stomach; this is seen in advanced stages of hypertrophic pyloric stenosis. (Courtesy Mark A. Hostetler, MD.)

Management

Treatment consists of fluid and electrolyte replacement and surgical consultation. Fluid resuscitation should begin with a bolus of 20 mL/kg of normal saline, followed by additional boluses as necessary to treat signs of shock. When the patient is stable and shows no signs of shock, 5% dextrose and half-normal saline at 1.5 to 2 times maintenance may be administered. Potassium supplementation is often necessary. Hypertrophic pyloric stenosis is a chronic, progressive disease, not an acute ischemic process. Confirmatory radiographic diagnosis with ultrasonography may be done on a semiurgent basis as the patient's condition warrants. Pediatric surgical consultation is recommended although usually not emergent. The definitive corrective surgical procedure is the Ramstedt pyloromyotomy, which has an excellent track record of safety.[7] More recently, laparoscopic pyloromyotomy has gained increasing acceptance as being safe and effective.[8] Associated mortality is rare.

Disposition

Most children probably are best managed with hospital admission for rehydration and correction of electrolyte abnormalities. Imaging and surgical consultation are obtained on a semielective basis.

Table 172-3 Differential Considerations for Vomiting by Age

Malrotation with Midgut Volvulus

Perspective

Malrotation occurs in 1 in 500 live births and has a male predominance by at least 2:1.[9] Among infants with malrotation, volvulus eventually will develop in approximately 75%, and 75% of these infants present within the first month of life. Overall, 90% of patients present within the first year of life, although cases of adult midgut volvulus have been reported.[9] Bilious emesis is the hallmark presentation and is seen in more than 75% of cases.[6,9,10] Malrotation with volvulus carries a mortality rate of 3 to 15%.[9]

Principles of Disease

During embryologic development, the gastrointestinal tract rotates around the superior mesenteric artery. As it completes the rotation, the duodenum forms a C-loop and is fixed to the retroperitoneum in the left upper quadrant at the ligament of Treitz. The cecum becomes similarly fixed in the right lower quadrant. The duodenum and cecum normally come to lie widely separated and loosely connected by a broad-based mesentery. They are fixed firmly in position by peritoneal attachments called Ladd's bands. In cases of malrotation, the duodenum and the cecum do not rotate completely but end up close to each other, suspended in the midgut region by their vascular attachment containing the superior mesenteric artery. This unusually close proximity of the intervening mesentery results in a short stalk of mesentery that easily twists on itself, resulting in obstruction of the distal duodenum and compression of the superior mesenteric artery. Vascular compression results in ischemia of the bowel and, if it is not rapidly reversed, necrosis of the bowel wall in 1 to 2 hours.[9,11] Twisting of the pedicle also results in various degrees of obstruction secondary to Ladd's bands that are malpositioned and straddling the duodenum.

Bilious emesis is the hallmark presentation and is a result of severe obstruction. Any pigmented staining of the vomitus suggests the presence of bile. When bile is initially produced, it is bright yellow and turns green only with time and oxidative exposures. Differential coloring of bile-stained emesis, yellow versus green, is not predictive of surgical condition.

Clinical Features

Infants classically present with sudden-onset bilious emesis and abdominal distention.[12] The obstruction may be relatively high, however; consequently, a distended abdomen may not always be present. Infants usually appear quite ill and may present in shock.[13,14] Infants also may present with a history of intermittent, relatively mild episodes of emesis that suddenly become more intense. Although bilious emesis in a neonate suggests the possibility of acute obstruction and volvulus, presenting manifestations in children may be nonspecific, such as abdominal distention or an ill appearance.[12,13]

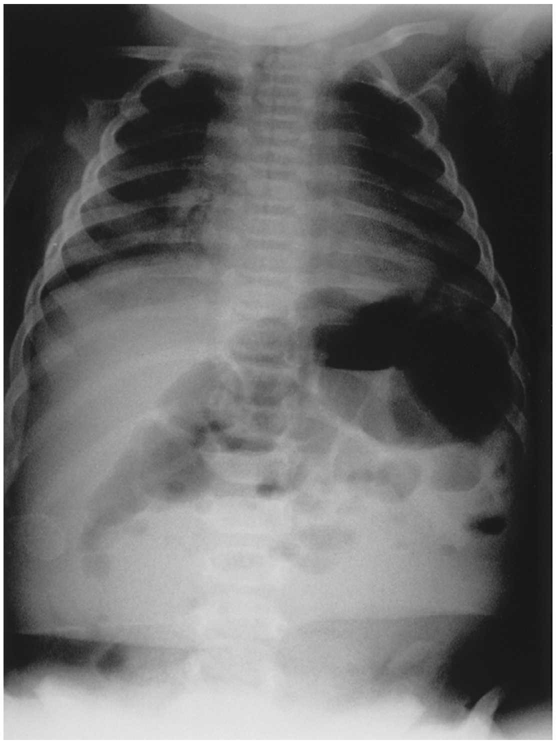

Figure 172-3. Upright abdominal radiograph obtained in an infant with bilious vomiting illustrates dilated loops of small bowel and a paucity of bowel gas distally, consistent with proximal obstruction secondary to malrotation with midgut volvulus. (Courtesy Mark A. Hostetler, MD.)

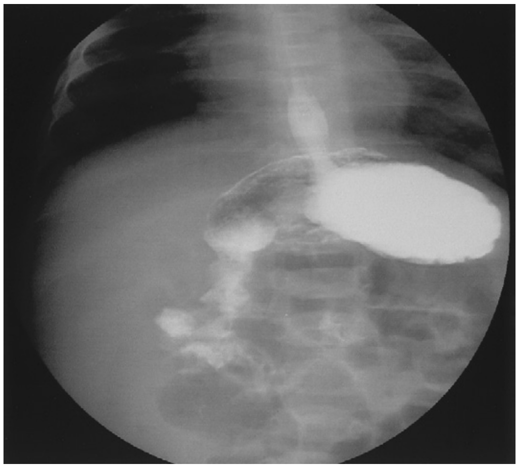

Figure 172-4. Upper gastrointestinal film, obtained in the same infant as in Figure 172-3, reveals abnormal positioning of the duodenal C-loop to the right of the spinal column, consistent with malrotation. (Courtesy Mark A. Hostetler, MD.)

Diagnostic Strategies

Diagnostic strategies may include a plain film of the abdomen, an upper gastrointestinal series, or a computed tomography (CT) scan of the abdomen. The imaging modality of choice is an upper gastrointestinal series with small bowel follow-through. Findings on plain abdominal films may include air-fluid levels suggesting obstruction, dilated loops overlying the liver, and a paucity of small bowel gas distally[11] (Fig. 172-3). In addition, a "double-bubble sign" may be present. The classic double bubble represents a dilated stomach and obstructed proximal duodenum and is seen with duodenal atresia and malrotation with midgut volvulus. Duodenal atresia is limited to the newborn nursery and is manifested within 24 hours of life. Malrotation with midgut volvulus typically is manifested with bilious vomiting within the first month of life. The modified double-bubble sign seen with hypertrophic pyloric stenosis represents a dilated body of the stomach and pylorus and is associated with nonbilious emesis.

The diagnostic procedure of choice to determine midgut volvulus is the upper gastrointestinal series, which reveals abnormal position of the duodenal C-loop (Fig. 172-4) and small bowel with a characteristic corkscrew appearance (Fig. 172-5).[11] It is very low

www.ketabpezeshki.com 66485457-66963820

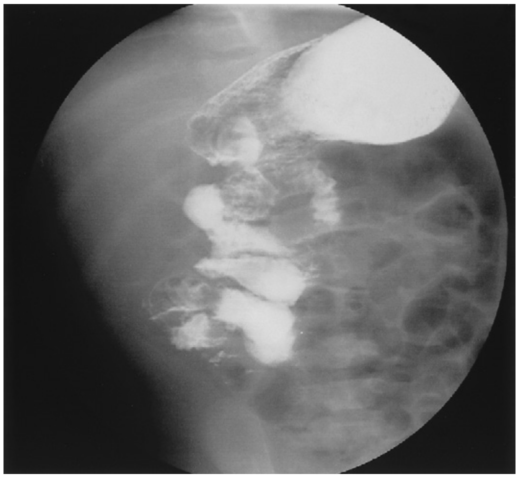

Figure 172-5. Another spot film from the upper gastrointestinal series obtained in the infant in Figure 172-3. This radiograph shows the characteristic corkscrew appearance seen on small bowel follow-through in patients with malrotation. (Courtesy Mark A. Hostetler, MD.)

risk, but an experienced technician or a radiologist is required to perform the test. An ultrasound scan may be obtained because of abdominal pain and may reveal abnormal positioning of the duodenal C-loop and superior mesenteric artery; a "whirlpool sign" is described with the spiraled mesentery causing an echogenic twisting pattern. The place of ultrasonography in the evaluation of children with midgut volvulus has yet to be determined.[10,15] CT is usually not recommended as it carries the risk of additional radiation without benefit of improved diagnostic ability over upper gastrointestinal series.

Differential Considerations

Vomiting in childhood is common and occurs across a wide spectrum of illnesses (see Table 172-3). Causes vary by the age of the child and whether the course of vomiting has been sudden in onset, gradually progressive, or chronic. Gastroesophageal reflux classically begins early in life, usually shortly after birth, and remains relatively constant. With pyloric stenosis, vomiting does not begin until the age of 2 to 3 weeks and then becomes increasingly severe, projectile, and nonbilious. Acute obstruction causes sudden-onset vomiting, which may be bilious. In a neonate, bilious vomiting requires diagnostic evaluation to rule out the possibility of malrotation with volvulus.[12,13] NEC is another consideration but most often is manifested within the first weeks of life. Neonates with NEC may present with obstructive signs and symptoms, including bilious emesis and abdominal distention. Whereas malrotation usually is associated with a paucity of small bowel air on plain films, NEC is characterized radiographically by diffusely dilated loops of small bowel. In addition, the presence of pneumatosis intestinalis is diagnostic of NEC but is not a feature of malrotation.

Management

Infants with bilious emesis of sudden onset who appear ill or have a distended abdomen require emergency consultation with a pediatric surgeon.[16] Intravenous access should be obtained and laboratory studies performed for CBC, electrolyte values, and liver function. Repeated fluid boluses of normal saline, 20 mL/kg, are necessary until adequate circulation has been obtained. A fingerstick sample for blood glucose determination and specimens for blood and urine cultures should be obtained. A nasogastric or orogastric tube should be placed. After consultation with a pediatric surgeon, an upper gastrointestinal series may be needed emergently. Ill-appearing infants require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Time is of the essence in the evaluation and operative management of these patients. Rapid pediatric surgical consultation should be obtained in any neonate or infant with bilious vomiting even before diagnostic studies have been performed, especially for infants who appear ill. In contrast to hypertrophic pyloric stenosis, in which surgery does not need to be immediate, operative intervention must be rapid to save the bowel from necrosis.

Disposition

Patients thought to have malrotation require definitive imaging and an immediate surgical evaluation. If the diagnosis is confirmed or equivocal, hospital admission and surgical management are required.

Necrotizing Enterocolitis

Perspective

NEC, the most common gastrointestinal emergency in neonates, affects 2000 to 4000 infants in the United States every year.[17] NEC also is the most common cause of intestinal perforation during the newborn period.[17] Because most affected infants are premature and acquire the condition in the neonatal intensive care unit, NEC usually is not considered a disease of the emergency department (ED). Many of these infants may be discharged relatively early, however, because they are "feeding and growing" and come to treatment in the first month of life. Ten percent of infants with NEC are full-term babies.[18] Development of NEC is related closely to gestational age. In infants born at 24 to 28 weeks of gestation, NEC develops within 2 to 3 weeks of life[19]; in those born at 29 to 32 weeks of gestation, it is seen within 1 to 3 weeks of life. Among more mature or full-term infants, NEC tends to develop in the first week of life.[17] Complications in children who survive NEC may include strictures (in 10-20% of cases), fistulas, and short gut syndrome.

Principles of Disease

The exact pathophysiologic mechanism of NEC is unclear but seems to be multifactorial. Proposed risk factors include prematurity, aggressive enteral feedings, birth-related hypoxic-ischemic insults, and infectious causes. Prematurity is the most common and universally accepted risk factor; 90% of all affected infants are premature at birth.[18,19] Rapid advancement of feedings also has been associated with increased rates of NEC.[20] Infection has been implicated as an important causative mechanism.[21] Evidence suggests that hypoxic-ischemic insults are not an independent risk factor for the development of NEC.[18] The primary pathologic event may be inflammation or injury to the intestinal wall, which begins in the mucosa and then extends transmurally. The distal ileum and proximal colon are more commonly affected, and the involvement may be continuous or patchy.[22]

Clinical Features

Infants with NEC present with feeding intolerance and emesis. Emesis may be either nonbilious or bilious. On occasion, individual loops of bowel become distended with air and are palpable on abdominal examination. In the more severe stages of the disease, infants may appear extremely ill, with hematemesis, hematochezia, and shock. NEC commonly is placed into one of

www.ketabpezeshki.com 66485457-66963820

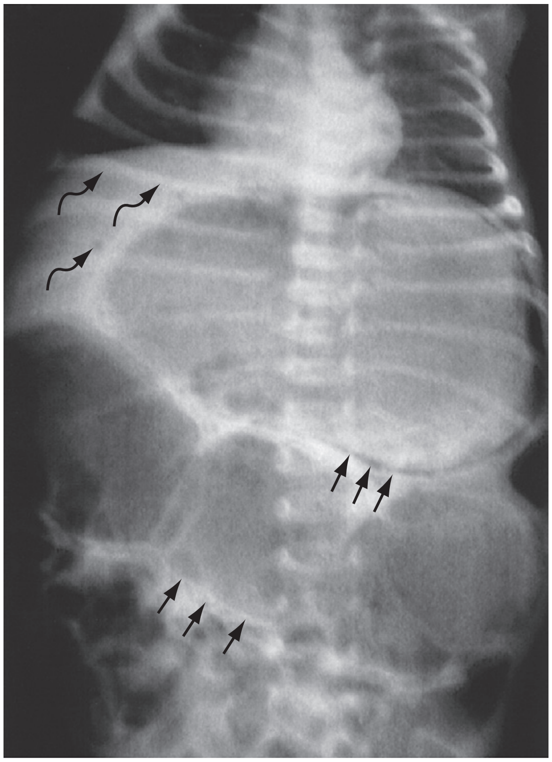

Figure 172-6. Plain radiograph obtained in an infant with necrotizing enterocolitis. Straight arrows indicate air within the wall of the small bowel and gastric mucosa (pneumatosis intestinalis and gastralis). Curved arrows indicate air in the biliary tree (portal venous gas). (Courtesy Mark A. Hostetler, MD.)

three clinical stages on the basis of criteria developed by Bell.[23] Stage I represents early or suspected NEC based on feeding intolerance, vomiting, or ileus. Stage II represents definite NEC as proved by abdominal radiographs showing intestinal dilation and pneumatosis intestinalis. Stage III represents advanced disease and is associated with perforation. Infants in this stage are acutely ill, with marked abdominal distention, metabolic acidosis, disseminated intravascular coagulation, and shock.

Diagnostic Strategies

Dilated loops of bowel are a common but nonspecific finding in stage I. Another early and more specific radiographic sign is the loss of a normal symmetrical gas pattern and replacement with an asymmetrical pattern of bowel gas, with a variable degree of dilation. Intramural air (pneumatosis intestinalis) is specific for NEC and is present in stage II[23] (Fig. 172-6). Pneumatosis is present in 75% of patients with NEC.[18] Air also may be seen within the biliary tract (portal vein gas) or occasionally in the gastric wall (pneumatosis gastralis; see Fig. 172-6). Portal vein gas is present in 10 to 30% of cases.[18] Ultrasonography and barium enema, which have been described as adjunctive diagnostic imaging modalities in patients with suspected NEC, are rarely helpful in the ED. No individual laboratory features are diagnostic or specific for NEC.

Differential Considerations

Etiologic possibilities vary according to whether the emesis is bilious and the course of vomiting has been sudden in onset, gradually progressive, or chronic (see Table 172-3). Gastroesophageal reflux classically begins early in life, usually shortly after birth, and remains relatively constant in character. Pyloric stenosis—related vomiting does not begin until 2 to 3 weeks of age and then becomes increasingly severe and projectile. In neonates, bilious vomiting requires careful consideration to rule out the possibility of malrotation with volvulus. As noted previously, with malrotation, a paucity of small bowel air usually is noted on plain films, whereas with NEC, diffusely dilated loops of small bowel typically are seen. In addition, the presence of pneumatosis is diagnostic of NEC but is not a radiographic feature of malrotation.

Management

Patients thought to have NEC should receive nothing by mouth (i.e., NPO [*nil per os*] status), with placement of either an orogastric or a nasogastric tube for decompression of the stomach and small bowel. These patients frequently appear quite ill and may have periods of apnea or significant respiratory distress. The airway should be secured as indicated. Intravenous access should be established and routine laboratory studies performed to include CBC, electrolyte panel, type and screen, and coagulation studies (prothrombin time [PT] and partial thromboplastin time [PTT]). A bedside blood glucose value should be obtained. Cultures of the blood and urine also are indicated. Careful attention should be given to management of fluids and electrolytes because considerable third spacing of fluids may occur in these patients. Repeated fluid boluses at 20 mL/kg of normal saline should be administered until adequate circulation is obtained. These boluses may be augmented with dopamine or epinephrine drips as necessary for patients in refractory shock when euvolemia has been achieved. Fluids should be continued with 5% dextrose in water and half-normal saline at a minimum of 1.5 to 2 times maintenance. Infants with NEC require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Emergent consultation should be obtained from a pediatric surgeon. Patients with evidence of perforation, peritonitis, or gangrenous bowel require surgical intervention. Only one half to three quarters of patients with perforation have free air detectable on radiographs.[23]

Disposition

Children thought to have NEC require admission to an intensive care unit (either pediatric or neonatal) and pediatric surgical consultation.

Gastroesophageal Reflux

Perspective

Gastroesophageal reflux, one of the most common causes of vomiting during infancy, refers to the regurgitation of stomach contents into the esophagus.

Principles of Disease

Gastroesophageal reflux occurs as a result of an incompetent lower esophageal sphincter. Chronic reflux of gastric contents into the esophagus may result in esophagitis, aspiration, and failure to thrive if it is severe.

Clinical Features

Clinical manifestations occur along a wide spectrum of disease, ranging from occasional episodes of spitting up to severe, persistent vomiting and failure to thrive. Gastroesophageal reflux generally responds to conservative measures and resolves with age. It

www.ketabpezeshki.com 66485457-66963820

usually begins shortly after birth and resolves by the age of 1 year. The disorder may be associated with stereotypical opisthotonic movements, collectively referred to as Sandifer's syndrome. Affected children exhibit extension and stiffening of the arms and legs and extension of the neck, often accompanied by a shrill or guttural cry. It may be associated with a brief period of apnea and pallor as formula is refluxed into the esophagus. Sandifer's syndrome most commonly occurs shortly after feeding and usually is not associated with cyanosis.

Diagnostic Strategies

In the ED, the diagnosis of gastroesophageal reflux typically is made on the basis of a careful history and physical examination. However, for ill patients in whom the diagnosis is uncertain, other diagnostic studies are available with gastroenterology consultation, such as esophageal pH probes to check for reflux of acid, barium swallow, and direct visualization by endoscopy.

Differential Considerations

Children with gastroesophageal reflux exhibit nonbilious emesis that begins shortly after birth and is relatively constant over time. Typically, no sudden starting or ending point, as would be suggested by an acute obstruction, can be identified. Vomiting usually is neither gradually progressive nor projectile, as seen with pyloric stenosis. Most children with gastroesophageal reflux of milder severity continue to gain weight.

Management

Most infants respond to conservative measures, such as smaller feedings, frequent "burpings," thickening of formula with cereal, and semiupright position for 45 minutes to 1 hour after feeding. Pharmacologic regimens are reserved for more severe cases. Weight loss is an important historical feature and necessitates pediatric gastroenterology referral for evaluation. Children exhibiting failure to thrive or esophagitis often are prescribed ranitidine and metoclopramide. Ranitidine, a histamine blocker, reduces gastric acid secretion. Metoclopramide increases lower esophageal tone, reduces pyloric sphincter tone, and increases gastric motility. Patients not responding to medical management occasionally require surgical intervention with a Nissen fundoplication, which involves wrapping of a portion of the stomach around the esophagus to prevent the reflux.

Disposition

Most children can be discharged home safely with conservative measures. Children who exhibit failure to thrive should be referred to a pediatrician or pediatric gastroenterologist for consideration of pharmacologic management. Children with dehydration and children in whom other diagnoses have yet to be excluded may benefit from hospital admission and further evaluation.

Intussusception

Perspective

Intussusception is the most common cause of intestinal obstruction in children younger than 2 years and occurs most commonly in infants 5 to 12 months of age.[11,23] An estimated incidence of 1 per 2000 children younger than 15 years, with a male predominance, has been reported.[23] Siblings of affected children have a relative risk 15 to 20 times higher than that in the general population. The mortality rate for untreated intussusception is high.

Principles of Disease

The exact etiology of intussusception is unclear, but the most prevalent theory relates to a lead point that causes telescoping of one segment of intestine into another.[23] As the process continues and intensifies, edema develops and obstructs venous return, resulting in ischemia of the bowel wall. As ischemia of the bowel wall continues, peritoneal irritation ensues, and perforation may occur.

In younger children, lead points are most often the result of enlarged Peyer's patches secondary to a recent viral infection. In children older than 5 years, an underlying lesion is found in more than 75% of cases; lesions include HSP vasculitis, Meckel's diverticulum, lymphoma, polyps, postsurgical scars, celiac disease, and cystic fibrosis.[23-27] Intussusception may occur at any point along the gastrointestinal tract. Ileocolic intussusceptions are most common. Ileoileal intussusception may occur in children with HSP.

Clinical Features

The classic triad of clinical findings in intussusception consists of abdominal pain, vomiting, and bloody stools. All three features are present in less than one third of patients, however. Three quarters of patients with intussusception have two of these findings, and 13% have either none or only one.[27] In a typical presentation, the child experiences cyclic episodes of severe abdominal pain. The pain typically lasts 10 to 15 minutes and has a periodicity of 15 to 30 minutes. During the painful episodes, the child is inconsolable, often described as drawing the legs up to the abdomen and screaming in pain. The clinical presentation occasionally does not include more typical evidence of pain; instead, the child presents with profound lethargy. Vomiting and diarrhea may be associated features. Blood may be present in either the stool or the emesis. Diarrhea containing mucus and blood constitutes the classic "currant jelly" stool most often associated with intussusception, although in actuality this finding is relatively infrequent. Children often have had a recent viral illness. Palpation of the abdomen may reveal a sausage-like mass in the right upper quadrant representing the actual intussusceptus and an empty space in the right lower quadrant representing the movement of the cecum out of its normal position. This combination of findings is called Dance's sign and is considered pathognomonic for intussusception. Its occurrence is relatively uncommon, however. Intussusception usually is not associated with a high fever; however, low-grade fevers may occur.

Diagnostic Strategies

Initial screening films should be obtained, with a minimum of two views of the abdomen. Attention should be focused on visualization of the entire colon and in particular the cecum. Films also should be examined for evidence of a soft tissue mass or mass effect, obstruction, target sign (representing air in the intussusceptum as it telescopes into adjacent bowel), meniscus sign (representing air compressed like a meniscus from invaginating bowel), and free air (Fig. 172-7). Normal findings on radiographs of the abdomen revealing complete visualization of the entire colon, including the cecum, make intussusception unlikely; however, indeterminate or nonspecific findings on films in which the entire colon cannot be visualized do not rule out intussusception and require additional imaging. Ultrasonography is the least invasive and most commonly used modality to visualize intussusception and is highly accurate.[28] Ileocolic intussusceptions are most common and are easily detected by ultrasonography, even in inexperienced hands.[29] The goal of the ultrasound examination is to visualize the ileocecal junction, which should be in the

www.ketabpezeshki.com 66485457-66963820

Figure 172-7. Plain radiograph obtained in a child with crampy abdominal pain and vomiting, later confirmed to have intussusception. Findings include a poorly defined soft tissue density in the right upper quadrant, obscuration of the liver edge, and focally dilated loops of small bowel, consistent with an acute obstructive process (intussusception). (Courtesy Mark A. Hostetler, MD.)

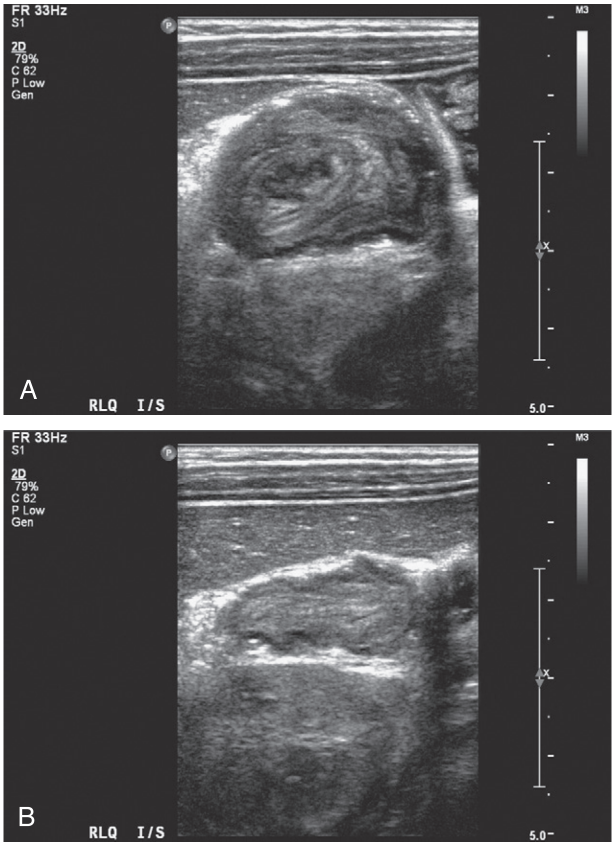

Figure 172-8. Abdominal ultrasound examination in a child with colicky abdominal pain and vomiting, later confirmed to have intussusception. On the transverse view (**A**), findings include a complex mass with a multilayered or rolled appearance. In the long view (**B**), the ileum can be seen protruding up into the cecum, forming the intussuscipiens-intussusceptum complex. (Courtesy Mark A. Hostetler, MD.)

right lower quadrant but may be translocated into the right middle to upper quadrant. On the ultrasound scan, the intussusception appears on the transverse view as a multilayered or wrapped complex mass and on the longitudinal view as a tube within a tube as the ileum projects up into the cecum (Fig. 172-8). Because of the readily identifiable anatomic location and the absence of ionizing radiation, this is usually the diagnostic imaging modality of choice. Contrast enemas may be both diagnostic and therapeutic and, with a high index of suspicion (i.e., children with the triad of paroxysms of pain, vomiting, and blood in stool), may be done as first-line therapy. The enema will reveal a sharp cutoff at the point where the intussusceptum meets the contrast material (Fig. 172-9). Air-contrast enemas are equally efficacious, have success rates averaging more than 60%, and are preferred to barium contrast studies by some physicians.[28-31] Either type of enema requires readily available backup by a pediatric surgeon in the event of failure of the bowel to reduce or perforation. Before any radiologic studies are performed, intravenous access should be established, and the patient should receive at least one bolus of 20 mL/kg of normal saline along with appropriate parenteral pain relief.

Figure 172-9. Contrast enema image obtained in a child with intussusception shows a sharp cutoff where the contrast material meets the intussusceptum and the acute obstruction. (Courtesy Mark A. Hostetler, MD.)

Differential Considerations

Differential considerations for abdominal pain in children by age are listed in Table 172-4. Slow, progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. Children with peritoneal irritation invariably lie still, often on the side with the knees bent, and refrain from all extraneous movement. Sudden onset of severe pain is associated most often with acute obstruction or vascular occlusion, as seen with intussusception, volvulus, or torsion of the testicle or ovary. Children with intussusception have severe colicky pain and often rock back and forth, frequently moaning or crying. Children with ischemic pain exhibit symptoms out of proportion to the findings on examination. They may appear diaphoretic, clammy, or pale and complain of excruciating abdominal pain although exhibiting only mild tenderness to palpation and no localizing findings.

Management

Patients require intravenous access and screening CBC and electrolyte values. Intravenous fluids are given in boluses of 20 mL/kg of normal saline until adequate vascular volume is achieved. Children should be maintained on NPO status. Nasogastric tube decompression may be necessary if there is evidence of significant gaseous distention. Prompt surgical consultation is required. Ill-appearing or febrile children require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Diagnostic and therapeutic interventions depend on location and resources available. Patients may undergo an initial ultrasound examination, or if history and plain film findings suggest intussusception, the patient may go straight to either air or hydrostatic barium enema. Surgical intervention is required if the reduction is unsuccessful or if perforation occurs. The overall success rate for air-contrast enema or barium enema approaches 90%. Intussusception may recur in 7 to 10% of radiologic reductions and in 2 to 5% of surgical reductions, usually within 24 hours. Admission for observation usually is recommended for all patients after reduction.[30]

Disposition

Children with suspected intussusception require definitive imaging with ultrasonography. Children with documented intussusception require reduction with either enema or surgery. Hospital admission is recommended for all patients after reduction.

Hirschsprung's Disease

Perspective

Hirschsprung's disease accounts for approximately 20% of cases of partial intestinal obstruction in early infancy. Hirschsprung's disease occurs at a rate of 1 in 5000 live births and is four to five times more common in boys. It usually is sporadic in occurrence but may be associated with Down syndrome or a variety of other anomalies of the gastrointestinal, genitourinary, or central nervous system.[32]

Principles of Disease

Hirschsprung's disease represents congenital aganglionosis of the colon and is characterized by an absence of ganglion cells in the myenteric plexus of the distal colon.[32] The anus is invariably involved, with aganglionic bowel usually extending proximally 4 to 25 cm. Absence of colonic ganglion cells interferes with that segment's ability to relax, creating a functional obstruction. Stool accumulates proximal to the level of obstruction and produces dilation of the colon, the so-called megacolon.

Clinical Features

Neonates with Hirschsprung's disease often present in the nursery with failure to pass meconium. Infants brought to the ED may have a history of constipation and obstipation. Vomiting, irritability, and abdominal distention may be features. Symptoms and signs may be subtle and include a history of chronic constipation and poor weight gain or failure to thrive. Hirschsprung's disease usually is diagnosed in infancy; however, a spectrum of disease is recognized, and presentation may be later in life. Children who appear ill with fever should be evaluated for enterocolitis and toxic megacolon. Enterocolitis is characterized by abdominal distention, bloody stools, fever, and elevated white blood cell count.

Diagnostic Strategies

Plain films of the abdomen may reveal evidence of fecal impaction with proximal obstruction, air-fluid levels, and dilated colon. A barium enema revealing a narrowed aganglionic segment with proximal dilation is highly suggestive of Hirschsprung's disease.[32,33] The diagnosis is confirmed by biopsy or manometry.

Differential Considerations

Constipation is one of the most common causes of abdominal pain and vomiting in children.[33,34] Children in the process of "potty training" occasionally become pathologic in their ability to delay defecation. Pathologic causes of constipation are

www.ketabpezeshki.com 66485457-66963820

uncommon. In addition to Hirschsprung's disease, considerations include cystic fibrosis, infantile botulism, and hypothyroidism. An acquired variant of the disease also may occur in which other factors produce similar dilated colonic findings, resulting in acquired megacolon. Risk factors include anal fissures, fecal impaction, toilet training issues, and neuromuscular dysfunction secondary to neurologic disease, drugs, or metabolic causes.

The exact definition of constipation is elusive because it varies with age and diet. Infants during the first few months of life may have stool frequencies that range from one per feeding to one every other day, with breast-fed infants having more frequent stools than formula-fed infants. Frequency continues to decrease with age such that stools may average two or three per day during the first year of life and one or two per day from 1 to 5 years of age. Defecation occurs as a combination of physiologic, behavioral, and psychological factors. Relaxation of the external sphincter required for defecation is under voluntary control, whereas relaxation of the internal sphincter is involuntary. Children with a history of unpleasant or painful experiences associated with defecation may contract the external sphincter voluntarily in an effort to delay defecation for as long as possible. Accumulation of stool over time causes the rectum to dilate and decrease its propulsive activity, resulting in an increasing capacity for stool and chronic constipation. Acute episodes may be the result of dietary changes, travel, lack of normal exercise, or stress.

Management

Initial management is focused on ensuring adequate fluid and electrolyte status. Abdominal films should be obtained. With evidence of acute obstruction, seen as marked dilation, decompression may be necessary. Decompression usually can be accomplished easily with a rectal tube. Children who appear ill with fever should be evaluated for enterocolitis and toxic megacolon. Enterocolitis is characterized by abdominal distention, bloody stools, fever, and an elevated white blood cell count. Patients with enterocolitis require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Urgent consultation should be made with a pediatric surgeon. Definitive therapy is surgical, with resection of the aganglionic segments. Acquired megacolon is managed by decompressing the colon and addressing the underlying problems.

Management of constipation requires three considerations: cleanout, maintenance, and behavior modification. Acute constipation is easier to manage because fewer functional problems are involved. The acute management of constipation usually is relatively easy and requires primarily the cleaning out of stool. Most experts recommend an approach that includes stool softeners or laxatives from above and suppositories or enemas from below. In milder cases, only the administration of enemas is necessary to soften feces and to stimulate defecation. Tap water, Castile soap, and oil enemas are generally equally efficacious. Maintenance includes keeping the stool soft for as long as necessary with use of stool softeners or laxatives. Dietary modifications include increasing fiber and water in the diet and avoiding foods that may be constipating. Management of chronic constipation is more difficult and usually requires a multidisciplinary approach with attention to behavior modification. Children with an underlying pathologic process, such as cystic fibrosis, may benefit from more intense measures, such as administration of large volumes of polyethylene glycol (GoLYTELY).

Disposition

Unless children appear ill, most can be managed safely on an outpatient basis.

Meckel's Diverticulum

Perspective

Meckel's diverticulum is the most common congenital malformation of the small intestine and follows the rule of 2's: The diverticulum is 2 cm wide and 2 cm long and usually located within 2 feet of the ileocecal valve. Moreover, the condition occurs in 2% of the population, and only 2% of affected patients ever become symptomatic.[35] Half of all patients with the condition become symptomatic by the age of 2 years, and most present by the age of 20 years.[35]

Principles of Disease

Diverticula are remnants of the omphalomesenteric duct and contain bowel wall, with 60% containing heterotopic tissue.[36] This tissue most commonly involves gastric mucosa, but other types include pancreatic, duodenal, and endometrial tissue.[34-36] Bleeding occurs when acid secretion from ectopic gastric mucosa causes ulceration and erosion.

Clinical Features

Patients are classically boys younger than 5 years who present with massive, painless rectal bleeding of acute onset; however, it can occur at any age. Some children may have some complaints of abdominal cramping. In older children, the presentation may be similar to appendicitis. The blood often is described as brick red. Complications may include intussusception, obstruction, perforation, and peritonitis.

Diagnostic Strategies

A technetium scan, also known as Meckel's scan, is the diagnostic modality of choice and has an accuracy of 90% when ectopic gastric mucosa is present.[37] Administration of pentagastrin, cimetidine, or glucagon may increase the sensitivity of the test.[38] CT scan of the abdomen may be obtained to look for signs of obstruction or if the diagnosis is unclear. Definitive diagnosis is confirmed by laparoscopy or laparotomy.

Differential Considerations

Gastrointestinal bleeding is uncommon in childhood. The first step in evaluation of a child with suspected gastrointestinal bleeding is to determine whether the substance is actually blood. Children commonly eat or drink substances containing dyes that lead to factitious changes in the stool's color. A simple Hemoccult test of the stool or Gastroccult test of the emesis can document the presence of hemoglobin. False-positive results may occur with red meat and iodine. Patients consuming products with bismuth (Pepto-Bismol), iron, and spinach may have black stools falsely appearing melanotic; the Hemoccult test result is negative.

After it has been determined that the substance is blood, the second step is to determine its origin. The location of bleeding often is difficult to determine but may be theorized on the basis of the appearance of the blood. Hematemesis implies bleeding proximal to the ligament of Treitz. Blood exposed to gastric acids for any time develops the classic coffee-grounds appearance. Bright red upper gastrointestinal bleeding implies either more proximal bleeding, such as from varices or esophagitis, or brisk gastric or duodenal bleeding. Bleeding that originates beyond the ligament of Treitz but proximal to the ileocecal valve results in melena. Hematochezia, with a visibly red to maroon appearance of the blood, implies bleeding from the descending colon. Distal lesions, such as fissures or hemorrhoids, can result in bright red

blood. Barium contrast studies of the upper and lower gastrointestinal tract sometimes are helpful; however, nuclear medicine scans (Meckel's scan) are the procedure of choice for detection of Meckel's diverticulum. Endoscopic examination has the highest rate of determining the location of bleeding; however, the diagnosis often is confirmed first on Meckel's scan.

In neonates, the most common etiologic category of gastrointestinal bleeding is idiopathic. Careful examination of the rectum should be performed because the most identifiable cause of bleeding is a fissure or excoriation of the perirectal area. In young neonates, an Apt test may be performed to determine if the blood is maternal or fetal: 1% sodium hydroxide is added to the bloody stool. Fetal hemoglobin resists oxidation and remains pinkish red, whereas maternal hemoglobin changes to dark brown.

Another common cause of gastrointestinal bleeding in infancy is milk protein allergy. Affected children typically are younger than 6 months with a history of sudden-onset mucoid, blood-streaked stools. Children otherwise appear well. Although the causative allergy most commonly is to milk protein, gastrointestinal bleeding may occur with consumption of any protein and has been described in relation to soybean-based products. Children with persistent perianal excoriations and fissures refractory to standard emollients may be infected with group A streptococci and may benefit from treatment with an oral penicillin. Table 172-5 lists the differential considerations for gastrointestinal bleeding in children by age.

Management

Management of gastrointestinal bleeding begins by assessment of circulatory status and ensuring that it is adequate. Screening laboratory studies should include CBC, coagulation studies (PT and PTT), and type and screen. Two radiographic views of the abdomen should be obtained in patients in whom obstruction or perforation is suspected. A technetium scan is the imaging modality of choice to evaluate for Meckel's diverticulum. Consultation with a pediatric surgeon should be obtained.

Disposition

Children with suspected Meckel's diverticulum should undergo Meckel's scan. Children with minor bleeding and normal findings on screening laboratory studies may be observed closely on an outpatient basis. Children with more active bleeding should be hospitalized for care by either a pediatric surgeon or a pediatric gastroenterologist.

Henoch-Schönlein Purpura

Perspective

HSP, also known as anaphylactoid purpura, is a systemic vasculitis commonly associated with abdominal pain and rash. It is most common in children 4 to 11 years of age but also may occur in adults. HSP occurs most commonly in the spring after a viral upper respiratory infection. It also has been associated with insect stings and certain drugs.[39]

Principles of Disease

HSP is a hypersensitivity vasculitis with immune complex deposition with immunoglobulin A, mainly affecting the arterioles and capillaries. Although it is most well known for its characteristic petechial to purpuric rash, HSP is a systemic vasculitis and may affect any blood vessel. Less common manifestations are seen in cases in which the disease is more severe or widespread.

Clinical Features

Symptoms include abdominal pain, nausea, vomiting, and diarrhea. Patients most often are diagnosed clinically on the basis of the classic rash, abdominal pain, microscopic hematuria, and arthralgias. The classic rash is palpable purpura located on the buttocks and lower extremities (Fig. 172-10). Up to 70% of patients with HSP have gastrointestinal complaints. Microscopic

www.ketabpezeshki.com 66485457-66963820

Figure 172-10. Henoch-Schönlein purpura in a 7-year-old child. Note typical red-purple rash on the lower extremities. (Courtesy Marianne Gausche-Hill, MD.)

hematuria occurs in 50%.[40] Intussusception may occur and may be atypical in that ileoileal intussusception is more common than the ileocolic intussusception that normally occurs. The syndrome often is relapsing and remitting for several weeks and may be associated with arthralgias. Neurologic involvement also may be a feature of HSP, although this manifestation is uncommon in children.[41]

Diagnostic Strategies

Patients most often are diagnosed clinically on the basis of the classic rash, abdominal pain, microscopic hematuria, and mild arthralgias. Screening studies should include a CBC with differential and platelet counts, urinalysis, blood culture, and sedimentation rate determination. Children with worrisome abdominal pain require CT to rule out ileoileal intussusception.

Differential Considerations

The most important entity in the differential diagnosis for this type of rash is meningococcemia, in which the patient has a fever and looks very ill. It is essential to rule out meningococcemia because the condition is life-threatening and requires an entirely different approach to management involving hospitalization, fluid resuscitation, and intravenous antibiotics. The classic triad of palpable purpura, abdominal pain, and hematuria in an otherwise well-appearing child virtually ensures the diagnosis. Erythema nodosum occasionally is confused with the rash of HSP; however, the rash of erythema nodosum is described most often as subcutaneous purplish red nodules with the appearance of a bruise on the extensor surfaces of the distal extremities. Erythema nodosum usually involves only the shins but in more severe cases also may involve the forearms, hands, and feet.

Management

Most children with HSP can be managed with close follow-up and require no treatment other than symptomatic support. Severe or intermittent abdominal pain in children with HSP is suggestive of intussusception; imaging to investigate this possibility should be done with ultrasonography, followed by CT scan if the ultrasound study is normal because ileoileal intussusception may occur and is not detected easily by ultrasonography. Management with steroids is controversial. Corticosteroids, at a dose of 1 mg/kg/day (maximum, 60 mg), are reserved for patients with illness on the more severe end of the spectrum, with abdominal pain, hematuria, or arthralgias.

Disposition

Indications for hospital admission include uncertain diagnosis to exclude the possibility of meningococcemia, severe abdominal pain, and vomiting. Most patients can be managed safely with close outpatient follow-up.

Inflammatory Bowel Disease

Perspective

The two major entities included within the category of IBD are Crohn's disease and ulcerative colitis. Approximately 20% of patients present before the age of 20 years.[42] Most patients do not experience symptoms until adolescence, although childhood presentations have been described. IBD is rare in children younger than 1 year.[43]

Principles of Disease

Ulcerative colitis is an inflammatory disease primarily involving the mucosa and submucosa of the rectum and distal colon. *Crohn's disease* is a transmural inflammatory disease that may involve any portion of the intestinal tract. The most common area of involvement in cases with single-segment disease is distal ileum; however, multiple segments in different areas may be involved. Chronic inflammation may result in the formation of abscess, fistula, or stricture.

Clinical Features

Although patients experiencing complications frequently present to the ED, the diagnosis is rarely made in this setting. More commonly, children with known disease present in the midst of a flare, usually with bloody diarrhea and abdominal pain. Extraintestinal manifestations also occur and include fever, anemia, oral ulcerations, erythema nodosum, pyoderma gangrenosum, uveitis, liver dysfunction, and failure to thrive.[43] Some of these manifestations may occur even before the child has experienced any gastrointestinal symptoms. The most feared complication is toxic megacolon, which classically is manifested with abdominal pain, fever, and bloody diarrhea and is associated most often with ulcerative colitis.

Diagnostic Strategies

Flares of IBD are diagnosed by the increased frequency of diarrheal or bloody stools and abdominal pain. Patients who appear ill require plain films of the abdomen to rule out toxic megacolon. Patients with toxic megacolon usually have a fever, appear volume depleted, and demonstrate significant abdominal tenderness to palpation. X-ray films reveal dilation of the transverse colon to more than 6 to 7 cm in diameter. Free air also should be looked for because perforation may occur. Screening laboratory studies should include a CBC with differential and platelet counts, type and screen, coagulation studies (PT and PTT), and electrolyte panel.

www.ketabpezeshki.com 66485457-66963820

Differential Considerations

There are a wide number of differential considerations for abdominal pain and gastrointestinal bleeding (see Tables 172-4 and 172-5). Gastroenteritis is the most common consideration in this clinical scenario. Children experiencing their first episode of IBD are much more likely to be misdiagnosed with an acute gastroenteritis. Children outside the usual age at presentation also are more likely to be misdiagnosed with gastroenteritis. Children with recurrent symptoms or a family history of IBD should be referred to a pediatric gastroenterologist for further evaluation.

Management

Initiation of corticosteroid therapy in conjunction with a gastroenterologist constitutes the mainstay for treatment of acute exacerbations. Prednisone at a dose of 1 mg/kg/day (maximum, 60 mg/day) usually is recommended and should be provided in consultation with a pediatric gastrointestinal specialist. Other agents commonly used include sulfasalazine, azathioprine, and a host of other immunosuppressive agents. Management in the ED begins with attention to volume status and resuscitation with boluses of 20 mL/kg of normal saline until the volume status is adequate. Patients with suspected toxic megacolon require intravenous broad-spectrum, triple-antibiotic therapy (with ampicillin, gentamicin, and metronidazole) and immediate surgical consultation.

Disposition

Indications for admission include children who are dehydrated and toxic or ill appearing and those patients for whom the diagnosis is uncertain. Children with ongoing diarrhea productive of bloody stools usually benefit from intravenous fluids until the flare has been controlled. Children with evidence of toxic megacolon require surgical consultation and admission.

Gastrointestinal Foreign Bodies

Perspective

Most gastrointestinal foreign bodies occur in toddlers, who experience life by first putting objects in their mouths. Children younger than 3 years are particularly at risk because of the combination of inappropriate mouthing of objects and a general lack of coordination in swallowing. Although food is the most common esophageal foreign body in adults, coins are most common in children.[44,45] Children with mental retardation swallow a variety of objects. Adolescents occasionally swallow objects in an attempt at suicide. Rectal foreign bodies are uncommon in the pediatric age group.

Principles of Disease

Most swallowed foreign bodies pass without difficulty. Foreign bodies may become lodged in any of three areas of normal physiologic narrowing: upper esophageal sphincter (cricopharyngeus muscle)—thoracic inlet (C6-T1), aortic arch—tracheal bifurcation (T4-6), and lower esophageal sphincter—diaphragmatic hiatus (T10-11). In general, 80 to 90% of objects that have made it into the stomach are passed without difficulty.[46]

Clinical Features

The classic clinical presentation is that of a child who is seen from across the room putting coins in his or her mouth. Children frequently gag and sputter as they attempt to swallow the object. Aspirated objects generally produce persistent coughing, wheezing, or increased work of breathing. Objects that have been swallowed may result in the child's remaining asymptomatic or may produce symptoms ranging from persistent gagging to drooling, continuous dry heaves, or wheezing. Larger foreign bodies may compress the airway and cause significant respiratory distress. Rapidly progressive symptoms of dysphagia, pain, respiratory distress, or fever raise the possibility of a perforation. Perforation is uncommon, even with sharp objects such as straight pins. The ileocecal valve is the most common site for perforation, which occurs in less than 1% of patients.[46] Button batteries warrant special mention. Button batteries in the esophagus should be removed in as rapid a manner as possible because erosions and mediastinitis ultimately may occur. Button batteries in the stomach usually pass without difficulty and do not require removal unless they fail to pass the pylorus within 24 to 48 hours of ingestion.[47] The National Capital Poison Center in Washington, DC, operates a 24/7 website (http://www.poison.org/battery/) and hotline (202-625-3333) for battery ingestion cases. On occasion, objects pass into the stomach that are too large to pass through the pylorus; this is uncommon and is heralded by persistent vomiting. Long-present unrecognized foreign bodies may result in erosion, perforation, infection, stricture, or fistula formation.[48]

Diagnostic Strategies

Plain radiography is the most common method of visualizing location and is used to verify positioning past the lower esophageal sphincter into the stomach. Patients who are symptomatic after foreign body ingestion require imaging to determine location. On occasion, patients who are asymptomatic also have objects remaining in the esophagus.[49] Radiographs should include anteroposterior and lateral views of the chest, neck, and abdomen (Fig. 172-11). The lateral view helps delineate soft tissues in the hypopharynx and evaluate for swelling, particularly if the foreign body is either unknown or of a nonradiopaque material. A single view of the neck, chest, and upper abdomen often can be obtained easily in the pediatric patient. Unless the patient becomes symptomatic, repeated films are otherwise never necessary. Asking parents to sieve the stool typically is unproductive, and even sharp objects such as pins and razor blades usually pass through the gastrointestinal tract without incident. Patients presenting with a history of button battery ingestion represent the exception in that they require repeated films to document passage beyond the pylorus. Rather than using standard radiography, some institutions have noted success with intradepartment fluoroscopy or hand-held metal detectors.[49-51] Contrast studies may be helpful to delineate nonradiopaque foreign bodies or to evaluate for perforations.

Differential Considerations

Not all foreign bodies are radiopaque and visible with standard radiography. Patients who remain symptomatic require further contrast-enhanced imaging or direct visualization.

Management

If the object has made it into the stomach, usually it will pass without incident, and no further treatment is necessary. If the foreign body is in the esophagus, most experts recommend removal within 24 hours to decrease the risk of aspiration and esophageal erosion. The preferred method by which to remove esophageal foreign bodies is controversial and varies by institution. Options include fluoroscopic Foley catheter removal, bougie advancement into the stomach, endoscopic removal in the ED, and removal by rigid bronchoscopy under general anesthesia in the

www.ketabpezeshki.com 66485457-66963820

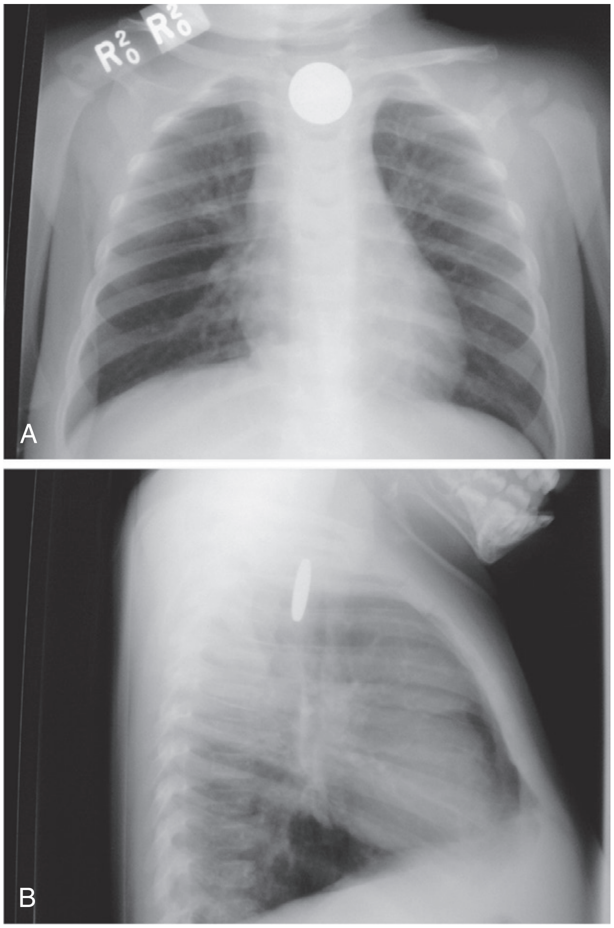

Figure 172-11. Plain radiographs obtained in a child with an esophageal coin foreign body. Posteroanterior (**A**) and lateral (**B**) views show the expected orientation for a coin lodged in the esophagus. (Courtesy Mark A. Hostetler, MD.)

operating room. Foley catheter removal and bougienage do not require sedation in cooperative patients, but young children invariably require sedation in the operating room. Children should be positioned on the side to decrease the risk of aspiration. With the last two methods, the technique involves actually holding onto the foreign body, which—at least theoretically—decreases the chance of inadvertent aspiration. They also have the additional benefit of directly visualizing the integrity of the mucosa and evaluating for perforation. Gastric foreign bodies generally do not require removal. Indications for surgical removal of gastric foreign bodies include objects that are more than 2 cm in width, objects that are more than 5 cm in length, and objects that are sharp (pins, razor blades).

Disposition

Esophageal foreign bodies require removal as described previously. After foreign bodies have made it into the stomach, most pass without difficulty, and no further follow-up is necessary. Button batteries constitute the exception and necessitate follow-up films to document passage beyond the pylorus.

Pancreatitis

Perspective

Pancreatitis is uncommon in childhood, especially in children younger than 10 years. Pancreatitis has an incidence of approximately 1 case in 50,000 in children and carries a mortality rate of 14%.[52,53] In adults, pancreatitis is associated most commonly with alcohol and biliary tract disease. In children, a fairly equal association of approximately 10 to 20% each has been documented for trauma, infection, structural disease, systemic disease, and drugs or toxins.[53] Mumps is the most common viral cause of pancreatitis and accounts for 10 to 15% of all cases.[53] Idiopathic causes account for 30% of cases. Biliary obstruction should be considered in the adolescent.

Principles of Disease

Whether the result of trauma, obstruction, or inflammation, a series of events occurs, resulting in inflammation, edema, and autodigestion of pancreatic tissue by pancreatic enzymes. In severe cases, the inflammatory process may progress to necrosis and hemorrhage, resulting in necrotizing or hemorrhagic pancreatitis. Further complications include the formation of abscesses, pseudocysts, and fistulas.

Clinical Features

Patients classically present with complaints of severe epigastric pain that radiates to the back. Pain is gradually progressive and constant and often is associated with nausea and vomiting. Pain classically is described as being worse with eating. Significant abdominal tenderness usually can be elicited in the epigastric area, accompanied by voluntary guarding and hypoactive bowel sounds. The abdomen may be slightly distended. Patients with biliary colic and gallstone pancreatitis have variable presentations from classic right upper quadrant pain associated with nausea and vomiting to intermittent epigastric pain and jaundice.

Diagnostic Strategies

Screening laboratory studies reveal elevations in serum lipase. Evidence of liver inflammation and elevated bilirubin and alkaline phosphatase may be seen in patients with biliary obstruction. Plain films of the abdomen may be indicated to investigate the possibility of free air or obstruction. An ileus pattern is common, often with a sentinel loop of dilated small bowel noted in the left upper quadrant. An ultrasound study or CT scan may be helpful to evaluate anatomy for congenital malformations or biliary tract disease and to evaluate for pseudocyst or abscess formation. In patients with pseudocysts, hemorrhagic pancreatitis may develop that may become life-threatening. For patients with respiratory distress, a chest film can be helpful to evaluate for a coexistent pleural effusion caused by the pancreatitis.

Differential Considerations

Slow, progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. Children with peritoneal irritation invariably lie still, often on the side with knees bent, and refrain from all extraneous movement. Sudden onset of severe pain is associated most often with acute obstruction or vascular occlusion as seen with intussusception, volvulus, or torsion. Differential considerations for abdominal pain in children by age are listed in Table 172-4; differential considerations for the causes of pancreatitis are listed in Table 172-6.

Management

Management begins with attention to volume status and correction of electrolyte abnormalities if present. A bedside finger-stick blood glucose value should be obtained. Adequate pain relief with parenteral narcotics should be provided. The patient should be

www.ketabpezeshki.com 66485457-66963820

Table 172-6 Differential Considerations for Pancreatitis in Children

ETIOLOGIC CATEGORY	SPECIFIC DISORDERS
Trauma	Handlebar injury
Infectious	*Viral*: mumps, influenza A, Epstein-Barr virus infection, cytomegalovirus infection, hepatitis A and B, rubella, rubeola *Bacterial*: salmonellosis, leptospirosis
Structural	Choledochal cyst, duplication cyst, anomalous bile duct, duodenal stenosis Pancreas divisum Tumor Cholelithiasis
Systemic, genetic	Cystic fibrosis Glycogen storage disease Familial hyperlipidemias α_1-Antitrypsin deficiency Sickle cell disease
Systemic, acquired	Systemic lupus erythematosus Kawasaki disease Hemolytic-uremic syndrome Henoch-Schönlein purpura Crohn's disease Reye syndrome Diabetes mellitus
Drugs or toxins	Steroids, oral contraceptives Valproic acid Sulfasalazine, azathioprine Rifampin, pentamidine, metronidazole, tetracycline Thiazides, ethacrynic acid, furosemide Alcohol, L-asparaginase
Idiopathic	No definitive cause found

maintained on NPO status and given adequate fluids. Intravenous fluids are given in boluses of 20 mL/kg of normal saline until adequate vascular volume is achieved and then are followed by 5% dextrose in water and half-normal saline at 1.5 times maintenance. Antiemetics are indicated to help control nausea and vomiting. A nasogastric tube usually is not necessary or helpful unless an ileus or persistent vomiting is present. Steroids and antibiotics are not indicated.

Disposition

Most children with pancreatitis require hospitalization unless they have known or recurrent disease for which an outpatient regimen providing adequate analgesia and hydration is available.

Appendicitis

Perspective

Appendicitis is the most common surgical condition involving the abdomen and the most common nontraumatic surgical emergency in children.[11] Approximately 200,000 appendectomies are performed every year, and appendicitis develops in approximately 1 of every 15 people in the general population sometime during their lifetime.[11,23,54] The peak age of incidence of appendicitis is between 9 and 12 years, and it is uncommon in children younger than 5 years.[11,23,54]

Acute appendicitis has an overall mortality rate of less than 1%. For unruptured appendicitis, the mortality rate is 0.1%; the mortality rate increases to approximately 3% for ruptured appendicitis. In children, the rate of appendiceal perforation before surgery varies, ranging from 17 to 40%, and is inversely related to age, with higher rates of perforation occurring in younger age groups. In children younger than 2 years, perforation will have occurred in 90% by the time of surgery.

Principles of Disease

The appendix is a blind pouch that may become obstructed. After it is obstructed, a vicious circle is established, with increasing edema, vasocongestion, inflammation, ischemia, infarction, necrosis, and perforation. In adults, a thicker appendiceal wall protects against perforation, and a well-developed omentum aids in walling off the infection to prevent its diffuse spread. Children have neither, so rupture tends to occur earlier and diffuse peritonitis develops more readily.

Clinical Features

Patients classically present with a constellation of symptoms that includes abdominal pain, nausea, vomiting, fever, and anorexia. All of these symptoms are gradually progressive during 4 to 24 hours. Abdominal pain usually is described as vague, crampy, and periumbilical on origination, which then becomes more severe, constant, and localized to the right lower quadrant. Fever usually develops later, sometimes not until after the patient already has presented to the ED. Nausea and vomiting are progressive and most often are associated with anorexia. Patients occasionally may have a multiphasic course to their illness, which begins with the classic abdominal pain, with progression of symptoms until they suddenly resolve, followed several days later by development of fever, chills, and abdominal pain. This course represents acute appendicitis with spontaneous rupture and formation of an abscess.

Physical examination may reveal several classic findings. In patients with inflammation surrounding the appendix, peritoneal findings that localize to the right lower quadrant are typical. Pain occurs with movement, so the patient prefers to lie still. Patients are unable to jump up and down and complain that even rocking the bed or tapping their heels causes pain. The abdomen usually is quiet, with an absence of bowel sounds. Rebound tenderness can be elicited in the right lower quadrant. Rovsing's sign also may be present and consists of severe pain in the right lower quadrant occurring when the examiner presses in the left lower quadrant and rapidly releases the examining hand. Other findings associated with appendicitis include the psoas and obturator signs. The psoas sign is pain elicited by having the patient, in lateral decubitus position, hyperextend the right thigh at the hip, thereby stretching the psoas muscle, which overlies the inflamed appendix. The obturator sign similarly is pain elicited by having the patient internally rotate the flexed right thigh against resistance. These signs are not frequently present but when present increase significantly the likelihood of appendicitis.

Diagnostic Strategies

Appendicitis may be diagnosed on the basis of history and physical findings alone. Patients with the appropriate constellation of findings consistent with appendicitis may not require any testing and can proceed directly to the operating room for either laparoscopic or open exploration. Patients in whom the diagnosis is suspected usually require some diagnostic workup. Screening studies should include a CBC with differential, urinalysis, and pregnancy test. An estimated 96% of patients with appendicitis have either an elevated white blood cell count greater than 10,000/μL or a left-shifted differential with more than 75% neutrophils.[55] Although an elevated white blood cell count supports the diagnosis, it is not specific for appendicitis. The appendix is close to the ureters, so

www.ketabpezeshki.com 66485457-66963820

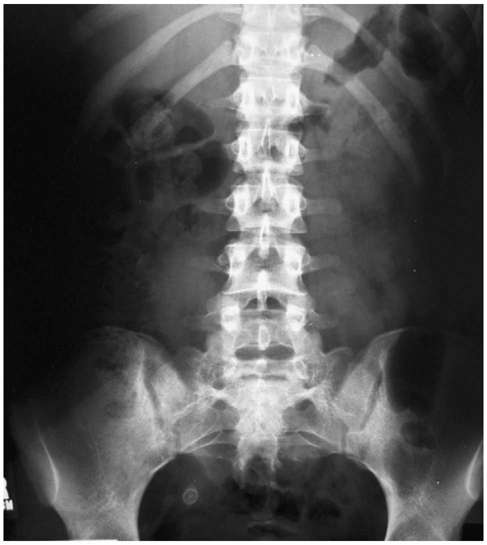

Figure 172-12. Fecalith in a child with appendicitis. (Courtesy Marianne Gausche-Hill, MD.)

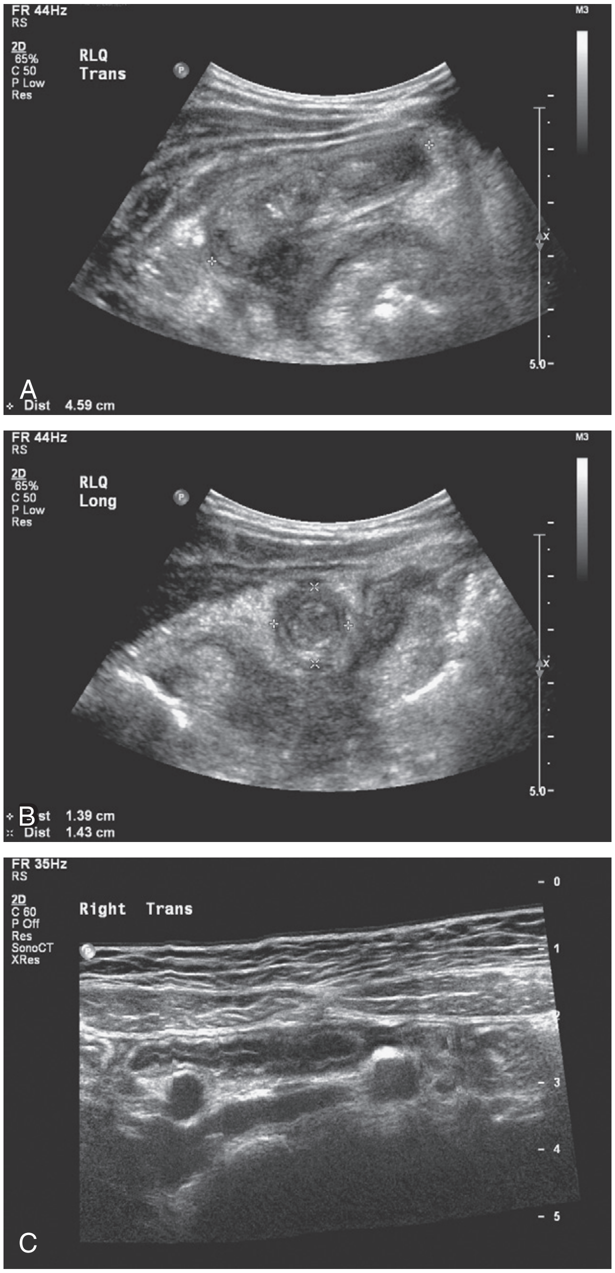

Figure 172-13. Ultrasound images obtained in children with appendicitis. Findings include an enlarged, noncompressible tubelike structure in the longitudinal view with an appendicolith (**A**), an enlarged, noncompressible structure seen in cross section (**B**), and, in another patient, an enlarged, poorly compressible structure with a moderate amount of free fluid consistent with acute perforation (**C**). (Courtesy Mark A. Hostetler, MD.)

appendicitis may induce some degree of sterile pyuria. Inflammatory changes related to appendicitis generally result in fewer than 5 to 10 white and red blood cells per high-power field and an absence of bacteria. Findings in excess of these amounts suggest a urinary tract etiology (e.g., infection, stone, mass, trauma). Consideration also may be given to a rapid streptococcal test in patients with a red or sore throat as streptococcal pharyngitis may present with abdominal pain.

Diagnostic imaging options include plain films of the abdomen, ultrasonography, and limited CT scan of the appendix. Plain films help rule out free air or obstruction and occasionally show an appendiceal fecalith, also called an appendicolith (Fig. 172-12). Although the presence of an appendicolith is essentially pathognomonic for acute appendicitis, it is present in only 10% of cases.[54] Ultrasound findings consistent with appendicitis include an enlarged, noncompressible appendix that is painful during scanning (Fig. 172-13A and B). A fecalith may be evident inside an enlarged and inflamed appendix, the so-called target sign.[56] Appendiceal ultrasound studies have a sensitivity, specificity, and overall accuracy of 90 to 95%.[56-59] Ultrasound imaging is particularly useful to evaluate for abscesses and fluid collections; however, a great deal of operator and reader variability is characteristic (Fig. 172-13C). Ultrasonography does not involve exposure to ionizing radiation. Use of an ultrasound examination as an initial screen for appendicitis, in which only patients with normal or equivocal scans were required to undergo CT, resulted in a sensitivity of 96% and a negative predictive value of 98%.[60,61]

Limited CT of the appendix is the most recent technology to have emerged in terms of imaging.[62-66] Limited CT scans of the appendix have sensitivity and specificity rates of 95 to 100%.[63-66] The ready availability of appendiceal CT has been shown to reduce the negative laparotomy rate from 20% to 7%; the highest accuracy is reported with use of new focused appendiceal CT techniques with rectal administration of contrast material.[66] For patients with relatively low probability of appendicitis, CT may offer a cost-effective screening tool, particularly compared with inpatient admission and observation.[62] Imaging of the pelvis and the right lower quadrant (with either CT or ultrasonography) not only establishes the diagnosis of appendicitis but also aids in identifying the two most common considerations in the differential diagnosis: IBD and mesenteric adenitis.[64-66] An important point is that CT scanning involves exposure to a significant amount of ionizing radiation, which places children at increased risk for future malignant neoplasms.[67] Beginning in the past decade, the number of CT scans has increased dramatically (nearly 700%), and appendicitis is believed to be the single primary reason accounting for its surge in use.[67] In weighing all of the risks and benefits, sequential imaging with ultrasonography followed by CT scan is likely to be the best choice.

Differential Considerations

Mesenteric adenitis is the most common condition associated with the signs and symptoms of appendicitis. It often is associated with significant diffuse tenderness and may localize in the right middle to lower quadrant. Children often lack fever, however, and

www.ketabpezeshki.com 66485457-66963820

do not have true peritoneal signs. Mesenteric adenitis usually follows a viral illness and results from nonspecific inflammation of mesenteric lymph nodes. It is perhaps even more common than appendicitis. Differential considerations for abdominal pain by age are listed in Table 172-4. Other considerations include nonaccidental trauma (abuse), malingering, and Munchausen syndrome.[67] Girls of reproductive age merit consideration of a gynecologic origin and require a pregnancy test and pelvic examination; the possibility of ovarian torsion, particularly if the pain seems to be severe and out of proportion to physical examination findings, should not be overlooked. Boys require an external genital examination to rule out the possibility of testicular torsion. Cryptorchidism in the face of acute abdominal pain should raise suspicion for testicular torsion.

Management

In patients with suspected appendicitis, NPO status should be maintained and an intravenous line established. Most patients have vomiting and anorexia and benefit from at least one fluid bolus of 20 mL/kg of normal saline and then administration of 1.5 to 2 times maintenance fluids with dextrose 5% in water and half-normal saline and administration of antiemetics. Screening studies should be initiated, and appropriate consultation with a surgeon is indicated. Ongoing pain should be addressed adequately. Intravenous narcotics are safe and effective and should not alter the diagnostic accuracy of the physical examination. Patients with high fever, suspected perforation, or unusual delay to surgery require coverage with intravenous broad-spectrum antibiotics, which should be initiated in the ED after consultation with the surgeon.[68,69] A reasonable regimen for antibiotic therapy consists of ampicillin, gentamicin, and either metronidazole or clindamycin. Nasogastric tubes are reserved for patients with persistent nausea or vomiting related to abdominal distention or ileus.

Disposition

Children with appendicitis as documented by physical examination or diagnostic imaging are hospitalized for appendectomy. Patients with nonspecific symptoms and signs who do not undergo definitive diagnostic study can be hospitalized and observed for a period of 12 to 24 hours or, with adequate family and social support, discharged home with careful instructions to return for re-examination.

Biliary Tract Disease

Perspective

Biliary tract disease is uncommon in childhood and has causes distinct from those of disease in adults. In children, gallstones are associated with hemolytic disease, cystic fibrosis, total parenteral nutrition, sepsis, and dehydration.[70,71] Ceftriaxone also has been associated with sludging and biliary disease, particularly in neonates. Acute acalculous cholecystitis has been associated with Rocky Mountain spotted fever and a variety of bacterial infections, including those due to *Salmonella* and *Shigella* organisms. Hydrops of the gallbladder (i.e., fluid distention of the gallbladder from chronic cystic duct inflammation or obstruction) is associated with viral upper respiratory or gastrointestinal infections, Kawasaki disease, streptococcal pharyngitis, mesenteric adenitis, nephrotic syndrome, and leptospirosis.

Principles of Disease

Gallstones are classified as either cholesterol or pigment stones. Pigment stones occur in childhood, whereas cholesterol stones usually do not begin appearing until adolescence. Pigment stones result from the excess breakdown of red blood cells and are seen most commonly in hemolytic anemia, such as from sickle cell disease and spherocytosis. Gallstones occurring in infants usually are associated with abdominal surgery, sepsis, NEC, or administration of total parenteral nutrition.[71] In young children, gallstones most commonly develop as a result of their hemolytic disease. Adolescents form gallstones in association with oral contraceptives, pregnancy, obesity, or underlying hemolytic disease. In acute acalculous cholecystitis, the ultrasound scan will reveal evidence of gallbladder inflammation in the absence of calculi. Hydrops of the gallbladder is an acute noninflammatory, noninfectious process that results in a markedly enlarged gallbladder without evidence of calculi.

Clinical Features

Similar to adult patients, pediatric patients usually present with right upper quadrant pain that radiates through to the back and may be associated with fever, nausea, and vomiting. Jaundice occurs in one third of patients.[71,72]

Diagnostic Strategies

Biliary tract disease usually is associated with elevations in liver enzymes and bilirubin; however, absence of elevations does not exclude the diagnosis. Accordingly, right upper quadrant ultrasound imaging should be undertaken in cases in which gallbladder disease is suspected. Elevations in alkaline phosphatase suggest cholestasis. Elevated white blood cell counts are nonspecific but if associated with fever may represent an acute infectious process (e.g., ascending cholangitis). Ultrasonography is the imaging modality of choice. It can reproduce pain on scanning (sonographic Murphy's sign) and determine the presence of gallstones, amount of dilation of the gallbladder and bile ducts, gallbladder wall thickness, presence of pericystic fluid consistent with the diagnosis, and anatomic configuration of the biliary and pancreatic collecting system. When ultrasound findings are equivocal or normal in the face of strong clinical evidence, the "gold standard" modality for biliary tract imaging is still considered to be cholescintigraphy (DISIDA scanning); rarely, percutaneous cholecystocholangiography is necessary.[71] Although only 15% of gallstones in adults are calcified and visible on plain radiographs of the abdomen, 50% of stones are visible in children.[72,73]

Differential Considerations

Biliary tract disease is uncommon in children and requires consideration of underlying or coexistent disease. Differential considerations for abdominal pain by age are listed in Table 172-4.

Management

Management of biliary tract disease begins with attention to fluid and electrolyte status. Adequate pain control should be provided, usually with a parenteral opioid. Asymptomatic patients with incidental findings of gallstones require no further therapy in the ED and may be referred to a surgeon for outpatient care. Patients who are afebrile usually can be managed safely on an outpatient basis with adequate pain control. Febrile patients require hospital admission and intravenous antibiotics. A reasonable regimen for empirical antibiotic coverage consists of ampicillin and gentamicin plus either clindamycin or metronidazole.

Several management options have been used in the treatment of children with cholecystitis: medical management with ursodeoxycholic acid to dissolve the stone, expectant management, and

www.ketabpezeshki.com 66485457-66963820

surgical management.[74] Laparoscopic cholecystectomy is considered safe and effective in children.[75]

Disposition

Indications for hospital admission include pain control, hydration, fever, and need for operation.

KEY CONCEPTS

- Physiologic jaundice of the newborn and breast milk jaundice are the most common causes of jaundice in the neonatal period.
- Direct hyperbilirubinemia in infants is always pathologic and requires a detailed workup.
- Hypertrophic pyloric stenosis is manifested with gradually progressive nonbilious emesis that becomes projectile.
- Hypochloremic, hypokalemic metabolic alkalosis is the classic electrolyte abnormality for children with hypertrophic pyloric stenosis.
- Bilious vomiting in the neonate should initiate a diagnostic evaluation for possible malrotation and volvulus.
- In infants with bilious emesis, a toxic appearance, a distended abdomen, or an acute obstructed pattern on abdominal radiographs constitutes a true surgical emergency.
- Necrotizing enterocolitis occurs more commonly in premature infants, but 10% of affected infants are full term.
- Gastroesophageal reflux usually responds to conservative measures (positioning, thickening of formula, smaller and more frequent feedings).
- The classic clinical triad in intussusception consists of abdominal pain, vomiting, and heme-positive stools; however, the triad occurs in less than one third of patients.
- Children with intussusception may present without pain and with lethargy alone.
- Hirschsprung's disease is a common cause of constipation in the neonate and usually is manifested by delayed passage of meconium.
- Meckel's diverticulum classically is manifested in children younger than 5 years with painless brick-red rectal bleeding.
- More than 90% of gastrointestinal foreign bodies pass without difficulty.
- Causes of pancreatitis in children include viruses, trauma, drugs, and toxins.
- Imaging strategies for children with suspected appendicitis that include initial ultrasound examination followed by CT scan of the abdomen have been shown to reduce costs and negative laparotomy rates.
- Cholelithiasis is diagnosed with right upper quadrant ultrasound imaging; management strategies include medical and surgical approaches.

Chapter 173

Infectious Diarrheal Disease and Dehydration

Patricia Padlipsky

ACUTE INFECTIOUS DIARRHEA

Perspective

Acute diarrhea is defined as the abrupt onset of abnormally high fluid content in the stool with increased volume or frequency or both. Episodes of diarrhea are classically categorized into acute or chronic on the basis of their duration. As supported by the World Health Organization, acute diarrhea is defined as an episode that has an acute onset and lasts no longer than 14 days; chronic or persistent diarrhea is defined as an episode that lasts longer than 14 days. This classification is important not only from the standpoint of epidemiologic studies but also from a practical standpoint because protracted diarrhea often has different causes, poses unique problems in management, and has a prognosis different from that of acute diarrhea. Acute infectious diarrhea can occur with or without vomiting. When it occurs with vomiting, it is often referred to as acute gastroenteritis. Children are at a higher risk than adults for complications from acute diarrhea with or without vomiting because of their smaller physical size, low physiologic reserve, higher metabolism, and immature immune system. Some of these complications include hypoglycemia, electrolyte abnormalities, metabolic acidosis, dehydration, and shock.

The prevalence of acute gastroenteritis in children has not changed much during the past four decades, but the mortality has declined sharply.[1] Although dehydration is the most common complication of acute infectious diarrhea, one of the most important reasons for the decline in mortality has been the increasing international support for the use of oral rehydration solutions (ORSs) as the treatment of choice for acute diarrhea. However, in emergency departments (EDs) across the nation, intravenous therapy is still routinely used for treatment of volume depletion due to infectious diarrhea. A few reasons that EDs still routinely use intravenous therapy instead of oral rehydration are the misconceptions that intravenous therapy is more effective, that it takes less time, and that it poses little risk. However, some potential serious complications have emerged as a result of overuse of parenteral rehydration. These include local complications from intravenous infiltrations (hematoma, thrombosis, phlebitis, postinfusion phlebitis, thrombophlebitis, infiltration, local infection, extravasation, and vasospasm) and systemic complications from overly aggressive replacement of volume deficits leading to central nervous system sequelae and pulmonary edema. In many situations, diarrhea-related volume depletion can be treated by enteral replacement by oral intake or delivered by nasogastric or orogastric tubes.

Epidemiology

In 2008, of the estimated 8.795 million deaths in children younger than 5 years worldwide, infectious diseases caused 5.970 million (68%) of these deaths. The largest percentages were due to pneumonia, diarrhea, and malaria (in decreasing order). Diarrhea was responsible for 15% or 1.336 million of these deaths.[2] Regional differences in resources, epidemiology, underlying general health status of the population, and availability of safe food and water affect the actual disease burden. In the United States, acute gastroenteritis historically accounts for approximately 10% of hospital admissions of children younger than 5 years, estimated at 220,000 admissions per year; 300 to 400 deaths per year are caused by diarrhea, most occurring in the first year of life.[2,3] In the United States, acute gastroenteritis is responsible for 3.7 million physician visits, 135,000 to 220,000 pediatric admissions (approximately 10% of total hospitalization for children younger than 5 years), and 150 to 300 deaths among children younger than 5 years.[3-5] Costs to society are significant, with approximately one billion dollars in total costs attributed to rotavirus alone.[6,7] The incidence of diarrhea in children younger than 3 years has been estimated to be 1.3 to 2.3 episodes per child per year; rates in children attending daycare centers are higher.

Pediatric death due to diarrhea is related to severe dehydration and associated complications. Improvements in recognition and treatment of dehydration have prevented many deaths in the United States. Risks factors for death from diarrhea include age younger than 1 year; birth weight less than 2500 g; African American, Hispanic American, or American Indian ethnicity; immunocompromise; and illness during winter months.[3,4]

In the United States, viruses are responsible for most cases of acute infectious diarrhea. Rotavirus, norovirus, astrovirus, and enteric adenovirus have been recognized as the most common agents responsible for viral diarrhea in children. Bacteria cause approximately 7 to 10% of cases of acute infectious diarrhea. The most common bacteria are *Escherichia coli, Campylobacter* species, *Salmonella* species, *Shigella* species, and *Yersinia enterocolitica*. *Clostridium difficile* is also seen as a cause of infectious diarrhea, especially in patients who have recently taken antibiotics and hospitalized patients. Parasitic causes of infectious diarrhea are uncommon in the immunocompetent patient, but they can occur. The most common parasitic organisms are *Cryptosporidium, Giardia,* and *Entamoeba histolytica*.[8-11] Infectious diarrhea in children is most often contracted through the fecal-oral route and through poor food-handling practices. Daycare centers remain a main source of cases, with infection spread by diaper handling, fecal-oral transmission, and sharing of toys. Causative agents may

www.ketabpezeshki.com 66485457-66963820

be endemic, epidemic with food- and water-borne outbreaks, or sporadic. For most agents, a large inoculum is required to transmit the illness. The exceptions are *Campylobacter, Giardia,* and *Shigella,* for which 10 to 200 organisms are sufficient to cause disease. Some groups are at higher risk for acquiring infectious diarrhea and suffer greater clinical consequences. Among these are premature infants, young infants (<3 months), and patients who are immunosuppressed or malnourished or who have a chronic disease. Recent hospitalization, treatment with broad-spectrum antibiotics, and travel to developing countries are additional risk factors.

Principles of Disease

Pathophysiology

The gastrointestinal tract normally takes in, secretes, and absorbs large quantity of fluids. Up to 9 L of fluid from diet and endogenous secretions enter the proximal bowel each day in the adult. In children, a proportionately larger volume of fluid per body weight is ingested and secreted to maintain homeostasis (e.g., 125 mL/kg per 24 hours in adults versus 220 mL/kg per 24 hours in newborns). Ninety percent of the fluid is absorbed in the small bowel and the remainder in the large bowel. Water follows osmotic gradients created by the transport of electrolytes, sugars, and amino acids into the bloodstream. Both active transport– and passive transport–facilitated mechanisms are in place. Glucose and certain amino acids are absorbed by active carrier-mediated transport and coupled to sodium absorption. This concept of cotransporter is important in understanding the role of the combination of dextrose and sodium in enteral rehydration.

Infectious agents cause diarrhea by adherence, mucosal invasion, enterotoxin production, or cytotoxin production or a combination thereof. Infectious diarrhea occurs when this balance is disrupted, either as a result of increased secretion from the gastrointestinal tract or because of decreased absorption of fluids. Although this distinction is useful conceptually, cases of infectious diarrhea often occur through both mechanisms.

Definitions. *Secretory diarrhea* is the result of increased intestinal secretion caused by a variety of mechanisms. In the case of *Vibrio cholerae,* an enterotoxin causes an increase in cyclic adenosine monophosphate (cAMP) in the endothelial cell, resulting in increased chloride and bicarbonate secretion. Clinically, secretory diarrhea is often characterized by the absence of expected reduction in stool volume with fasting, a stool pH above 6, and the absence of reducing substances in the stool. Other bacteria that produce enterotoxins include *Salmonella, Shigella, E. coli,* and *C. difficile.*

Osmotic diarrhea is caused by the presence of poorly absorbed solutes in the colon as a result of altered bacterial gut flora, damage to the mucosal absorptive surface, or ingestion of substances. These substances alter the normal mechanisms of fluid transport by creating an osmotic gradient across the bowel lumen. This results in movement of water and electrolytes into the luminal fluid. Typical acute viral gastroenteritis, caused by rotavirus or norovirus, produces injury to the small bowel epithelium with consequent disruption of microvilli. This disruption decreases the absorptive area and prevents normal fluid, electrolyte, and nutrient absorption. The illness is compounded when the colon is unable to cope with the large fluid volume. Diagnostic clues to an osmotic etiology are diarrhea that decreases or stops with fasting, a stool pH below 5, and the presence of reducing substances in the stool.

Dysentery is defined as diarrhea associated with blood and mucus in the stool. The presence of dysentery often implies that the infection has compromised the bowel wall. Acute inflammation, caused by enteroinvasive organisms such as *Salmonella, Shigella,* and *Campylobacter,* leads to infiltration of the gastrointestinal tract by neutrophils, which in turn release a host of enzymes and factors causing both increased secretion and decreased absorption by the intestinal tract. Although blood loss may be clinically appreciable, it is usually less significant than the fluid and electrolyte losses. Systemic infection should be suspected if the patient appears ill or has fever and chills or if an elevated count or a left shift is seen on a white blood cell count.

Before the diagnosis of acute infectious diarrhea is established, other potentially life-threatening illnesses that can be manifested with diarrhea with or without vomiting should be excluded. This can usually be accomplished with a thorough history and physical examination (Tables 173-1 and 173-2).

Table 173-1 Common Causes of Vomiting in Children

ETIOLOGIC CATEGORY	CLINICAL SYNDROMES
Central nervous system	Infections, space-occupying lesion
Gastrointestinal	Obstruction, peritonitis, hepatitis, liver failure, appendicitis, pyloric stenosis, midgut volvulus, intussusception, inborn errors of metabolism
Drug	Ingestion, overdose, drug effect
Endocrine	Addisonian crisis, diabetic ketoacidosis, congenital adrenal hyperplasia
Renal	Urinary tract infection, pyelonephritis, renal failure, renal tubular acidosis
Cardiac	Congestive heart failure of any cause
Infection	Pneumonia, acute otitis media, sinusitis, sepsis
Other	Psychogenic, respiratory insufficiency

Table 173-2 Common Causes of Diarrhea in Children

ETIOLOGIC CATEGORY	CLINICAL SYNDROMES
Gastrointestinal	Malabsorption (e.g., milk intolerance, excessive fruit juice), intussusception, inflammatory bowel disease, irritable bowel syndrome, short gut syndrome
Drug	Ingestion, overdose, drug effect
Endocrine	Thyrotoxicosis, addisonian crisis, diabetic enteropathy, congenital adrenal hyperplasia
Renal	Urinary tract infection, pyelonephritis
Infection	Pneumonia, acute otitis media, sinusitis, sepsis
Other	Parental anxiety, chronic nonspecific diarrhea

Physiologic Factors

Several physiologic factors predispose pediatric patients to more severe complications from vomiting and diarrhea. Children have larger extracellular fluid compartments compared with adults. As a result, children can lose proportionately more fluids through their gastrointestinal tracts. The turnover of fluids and solute in infants and young children can be as much as three times that of adults. This rapid turnover of fluids is the result of higher metabolic rates, increased body surface area to mass index, and higher body water contents (water constitutes approximately 70% of body weight in infants, 65% in children, and 60% in adults). Children also have limited stores of metabolic substrates such as fat and glycogen, limited ability to access fluids and the lack of

www.ketabpezeshki.com 66485457-66963820

intake when not feeling well, and kidneys that do not conserve water as well as adult kidneys. These factors make children more susceptible to large fluctuations in fluid, electrolytes, and nutrients.

Extracellular fluid loss in acute diarrhea may lead to significant intravascular volume depletion, which in turn may lead to primary metabolic acidosis with varying degrees of respiratory compensation. The metabolic acidosis usually results from the loss of bicarbonate (HCO_3^-) in diarrheal fluid but also may be caused by renal tubular acidosis, excessive lactate production from poor tissue perfusion, and therapeutic interventions (e.g., salicylates). One effect of metabolic acidosis is an increase in minute ventilation. On clinical examination, these children are hyperpneic, with deep and labored breathing, even when they are at rest. Patients with metabolic acidosis from diarrhea require restoration of intravascular volume to allow delivery of nutrient substrate and elimination of byproducts of cellular metabolism rather than rapid correction of the acid-base disorder with buffer. Restoration of intravascular volume often corrects what appears to be respiratory distress in the child who is severely volume depleted.

Etiology

A variety of viruses, bacteria, and protozoa can cause acute infectious diarrhea in children (Table 173-3). In developed countries such as the United States, viral causes predominate. In countries in which access to clean water and food supply is limited, bacterial agents contribute the major portion of the morbidity and mortality associated with infectious diarrhea.

Viruses

In the United States and Europe, the majority of cases of diarrhea with or without vomiting are caused by viral diseases that peak in the winter. The most common of these is rotavirus, which is the most common cause of infectious diarrhea worldwide. Other typical causes of acute infectious diarrhea include adenovirus serotypes 40 and 41, noroviruses, astrovirus, and adenovirus.

Rotavirus is the leading cause of diarrhea worldwide among children younger than 5 years.[12] In the United States, rotavirus is responsible for 410,000 office visits, 205,000 to 272,000 ED visits, and 55,000 to 77,000 hospitalizations each year. This virus is endemic and accounts for nearly one third of the cases in children with diarrhea. The number of cases of rotavirus infection peaks in the winter and spring. Rotavirus causes acute illness with vomiting and diarrhea that may or may not be associated with fever. The diarrhea is watery, and the volume may be large enough to result in significant and rapid intravascular volume depletion. Rotavirus also may cause symptoms of an upper respiratory tract infection. Most infections are transmitted person to person through the fecal-oral route. There is also evidence that it may be transmitted through respiratory secretions as airborne droplets. The incubation period is 1 to 3 days. Postinfection excretion may be prolonged up to 21 days after the onset of symptoms in the immunocompetent patient.[13]

Rotavirus selectively destroys the villus tip cells in the small intestine, leading to malabsorption and diarrhea. A proliferative response occurs, producing an abundance of incompletely differentiated cells in the gut mucosa. In the healthy host, repair of the epithelium and differentiation of the immature brush border take approximately 3 to 5 days and occur without specific intervention. In the chronically ill or malnourished child, the infection may lead to complications beyond the usual brush border injury. Failure to repair the epithelium leads to the vicious circle of malnutrition and progressive epithelial injury.[13]

Diagnosis is made by demonstration of antigens in stool specimens by enzyme immunoassay. Modern assays have up to 97% sensitivity and 97% specificity for rotavirus antigens in human stool. The test can be performed on undiluted stool without special preparation. Results are usually available within 24 hours.[13]

An effective vaccine was available for a short time (1998-1999) until it was noted to be associated with increased risk of intussusception, usually occurring 3 to 20 days after administration. This vaccine was subsequently withdrawn from the U.S. market.[14] Until recently, only two orally administered live virus vaccines were licensed for use among infants in the United States. RotaTeq vaccine was licensed in 2006 as a three-dose series, and in 2008 Rotarix, a live oral human attenuated vaccine, was licensed as a two-dose series for infants. The American Academy of Pediatrics does not express a preference for either vaccine. To date, no association with intussusception has been reported.[15,16] Preliminary surveillance data from the Centers for Disease Control and Prevention (CDC) have noted a 64% decrease among rotavirus-positive test results in the first year after vaccine release.[17] Recently, a new vaccine was introduced, the RV1 vaccine; studies in Brazil and Mexico show the risk of intussusception after RV1 vaccine to be 1 in 51,000 to 68,000. The authors concluded that this increased risk results in an annual excess of 96 hospitalizations and that this risk is outweighed by the benefit of the vaccine, which prevented 80,000 admissions and 1300 deaths.[17]

Noroviruses (previously known as Norwalk-like viruses) are the second most common cause of childhood acute infectious diarrhea. Norovirus accounts for approximately 12% of severe gastroenteritis among children younger than 5 years. In the United States, norovirus is responsible for more than 235,000 clinic visits, 91,000 ED visits, and 23,000 hospitalizations for children younger than 5 years.[18,19] Infection can occur year-round and in any age group but is most common during the colder months of the year. This virus causes the abrupt onset of watery diarrhea with or without vomiting. It is often accompanied by abdominal cramps and nausea. It is a self-limited disease, lasting 2 or 3 days. This virus can be transmitted person to person by the fecal-oral route as well as through contaminated food and water sources. In the United States, norovirus accounts for more than 90% of community outbreaks associated with viral gastroenteritis, which occur in all age groups. Common-source outbreaks in long-term care

Table 173-3 Common Causes of Infectious Diarrhea

Viruses (70-80% of infectious diarrhea in developed countries)
Rotavirus
Noroviruses
Astrovirus
Adenovirus
Hepatitis A
Bacteria (10-20% of infectious diarrhea; responsible for more cases of severe diarrhea)
Salmonella species
Shigella species
Campylobacter jejuni
Yersinia enterocolitica
Escherichia coli
Enterotoxigenic
Enteroinvasive
Enterohemorrhagic (*E. coli* O157:H7)
Clostridium perfringens
Clostridium difficile
Staphylococcus aureus
Vibrio cholerae
Vibrio parahaemolyticus
Parasites (<10%)
Cryptosporidium
Giardia
Entamoeba histolytica

facilities contribute significantly to morbidity and mortality among the residents. In addition, these agents most commonly are associated with outbreaks of acute gastroenteritis on cruise ships and in schools and hospitals. The incubation period is 12 to 48 hours, and the excretion of the virus lasts 5 to 7 days after the onset of symptoms in approximately 50% of infected people. In about 25% the excretion of the virus can be up to 3 weeks, and asymptomatic excretion can be longer in the immunocompromised.[20]

Astrovirus infections occur mostly in children younger than 4 years; cases peak in the late winter and early spring in the United States. The illness is characterized by diarrhea of short duration (a few days) accompanied by vomiting, fever, and occasionally abdominal pain. The incubation period is 1 to 4 days and transmission is person to person by the fecal-oral route. Viral shedding may begin a day before symptoms start and can continue for several days after cessation of diarrhea. However, asymptomatic shedding has been seen to last up to several weeks after the symptoms of the illness have resolved in healthy children There are no commercial tests for diagnosis in the United States, but enzyme immunoassays are available in many other countries. There are a few different tests available in some research and reference laboratories; the reverse transcription–polymerase chain reaction assay is the most sensitive.[21]

Adenovirus is well known for causing infections of the respiratory tract along with pharyngitis, otitis media, and pharyngoconjunctival fever. Enteric adenovirus serotypes cause gastroenteritis. These strains are transmitted through the fecal-oral route. Enteric disease occurs throughout the year and affects children younger than 4 years more commonly. The incubation period is 3 to 10 days. It is most contagious during the first few days of the acute illness, but asymptomatic shedding of the virus for months is not uncommon.[22]

The mainstay for treatment of viral enteritis is supportive care. Rehydration with ORS or intravenous fluids is recommended (see section on dehydration).

Bacteria

The common bacterial organisms causing acute diarrhea in the United States are *Salmonella* species, *Shigella* species, *Campylobacter jejuni, Yersinia enterocolitica,* and enterotoxigenic, enteroinvasive, and enterohemorrhagic strains of *E. coli*. Other, less common bacterial causes include *Clostridium perfringens, Clostridium difficile, Staphylococcus aureus, Vibrio cholerae,* and *Vibrio parahaemolyticus,* each accounting for less than 1% of cases of acute infectious diarrhea in children.

Salmonella infections usually are divided into those caused by nontyphoidal *Salmonella* and *Salmonella typhi* (typhoid fever). Nontyphoidal *Salmonella* account for more than 98% of the cases in the United States. Infection can result in an asymptomatic carrier state, acute gastroenteritis, bacteremia, and a disseminated abscess syndrome. It is thought that salmonellae invade the mucosa of the distal small intestine as well as the colon and produce a cholera-like enterotoxin and a cytotoxin. It is an illness marked by diarrhea, abdominal cramps, nausea, and fever; it may be manifested as dysentery or a cholera-like illness. Acute gastroenteritis occurs at any age but is most common in the first 4 years of life. Sustained or intermittent bacteremia can occur, and focal infections are seen in up to 10% of patients with *Salmonella* bacteremia. Animal reservoirs include poultry, livestock, and reptiles, which may be kept as pets by young children. Transmission is usually through foods such as poultry, beef, eggs, and dairy products. Other modes of transmission include ingestion of contaminated water and contact with infected reptiles, amphibians, and possibly rodents. The incubation period for gastroenteritis is 12 to 36 hours (range, 6-72 hours). Invasive disease and mortality are higher for infants and those with immunosuppressive conditions, hemoglobinopathies (e.g., sickle cell disease), malignant neoplasms, and human immunodeficiency virus (HIV) infection.[23]

Although it is uncommon, *Salmonella* serotype *typhi* can cause a bacteremic illness often referred to as enteric or typhoid fever. *S. typhi* is found only in humans, and infection implies direct contact with an infected person or with an item contaminated by a carrier. It is uncommon in the United States (approximately 400 cases per year) but is endemic in many countries. Consequently, typhoid fever infections in people in the United States usually are acquired during international travel. There is a gradual onset of symptoms that include fever, headache, malaise, anorexia, lethargy, abdominal pain, and tenderness. Patients may have hepatosplenomegaly, rose spots, and a change in mental status. It may appear as a nonspecific febrile illness in young children, in whom sustained or intermittent bacteremia may occur. Constipation is often seen early in the course of the disease, but diarrhea does occur in children.[23]

Treatment of nontyphoidal *Salmonella* infection is usually supportive. Antibiotics given to patients with nontyphoidal *Salmonella* infections have been found not only to be ineffective in shortening the duration of symptoms but also to prolong the carrier state. Therefore, antibiotics are generally not recommended for asymptomatic cases or for uncomplicated cases. Antibiotic treatment is indicated in infants younger than 3 months or those with complications (such as failure to improve within 5 to 7 days; bacteremia; focal infection in the central nervous system, bone, joint, kidney, or pericardium; and immunosuppressive conditions, hemoglobinopathies, malignant neoplasms, HIV infection, or chronic gastrointestinal disease). If treatment is necessary, ampicillin, amoxicillin, or trimethoprim-sulfamethoxazole usually is effective. Because of changing resistance patterns, susceptibility testing should be performed on all isolates. In areas where resistance to these antibiotics is common, ceftriaxone, cefotaxime, azithromycin, and fluoroquinolones are usually effective (fluoroquinolones are not recommended in people younger than 18 years) (Table 173-4).

For children with *S. typhi* infection, antibiotics are recommended. Multidrug-resistant isolates of *S. typhi* are common, often requiring empirical treatment with an antibiotic such as an expanded-spectrum cephalosporin, azithromycin, or fluoroquinolone. Relapse of enteric fever occurs in up to 15% of patients and requires re-treatment. Treatment failures have occurred in people treated with cephalosporins, aminoglycosides, and furazolidone despite in vitro testing indicating susceptibility.[23]

Shigella species consist of four antigenic groups of 40 serotypes. Among *Shigella* isolates reported in industrialized nations, including the United States, approximately 86% are *Shigella sonnei,* 12% are *Shigella flexneri,* 3% are *Shigella boydii,* and less than 1% are *Shigella dysenteriae*.[24]

S. sonnei is the most common cause of dysentery (diarrhea with significant blood, pus, and mucus) in the United States. Shigellosis usually begins as an enterotoxin-like secretory diarrhea with watery stools and fever that may progress to bacillary dysentery with or without systemic manifestations. Clinical illness varies from mild to severe, with some patients exhibiting abdominal cramps and tenderness. Shigellosis rarely infects infants younger than 3 months and is most common between 2 and 3 years of age. Symptoms usually are self-limited and resolve within 72 hours. Extraintestinal symptoms and signs are relatively common in children with *Shigella* infection and may include hallucinations, confusion, and seizures. Reactive arthritis can occur weeks after the infection. Rare complications of *Shigella* infection include bacteremia, hemolytic-uremic syndrome (HUS), and encephalopathy (Ekiri syndrome). Ingestion of as little as 10 to 200 organisms is all that is needed for infection to occur. Transmission occurs through the fecal-oral route, contact with contaminated objects, ingestion of contaminated food or water, and sexual contact.

www.ketabpezeshki.com 66485457-66963820

Table 173-4 Diarrheal Pathogens in Children and Specific Therapy

	SPECIFIC THERAPY BEYOND SUPPORTIVE CARE	COMMENTS
Bacteria		
Campylobacter jejuni	Oral: Azithromycin 10 mg/kg/day for 3 days *or* Erythromycin 30-50 mg/kg/day divided q8h for 5 days	Illness is usually self-limited. Treatment can shorten duration of illness and excretion of organism and prevent relapse.
Clostridium difficile	Oral or IV: Metronidazole 30 mg/kg/day divided q6h for at least 10 days (max. dose 2 g/day) *or* Oral: Vancomycin 40 mg/kg/day divided q6h for at least 10 days (max. dose 2 g/day)	Stop the offending agent. Up to 25% will have relapse after adequate treatment but usually will respond to a second course of the same medicine. Do not give antimotility agents.
E. coli—STEC	No antibiotic treatment; may increase risk of HUS	Antibiotics have shown no benefit and HUS may occur.
E. coli—ETEC (traveler's diarrhea)	Oral: Azithromycin 10 mg/kg/day for 5 days *or* Fluoroquinolones (>17 years) Oral ciprofloxacin 500 mg q12h for 1-2 days Oral norfloxacin 400 mg q12h for 3 days *or* Oral rifaximin (>12 years) 200 mg q8h for 3 days	As effective as ciprofloxacin.
Salmonella species, nontyphoidal	No antibiotics for asymptomatic or uncomplicated disease If antibiotics are given and susceptibility is known IV or oral: Ampicillin 200 mg/kg/day divided q6h Oral: TMP-SMZ, 10 mg TMP/kg/day divided q12h Susceptibility not known or areas of high resistance IV or IM: Ceftriaxone 100 mg/kg/day qd or divided q12h *or* Oral or IV: Azithromycin 10 mg/kg/day *or* Oral: Ciprofloxacin (>17 years) 500 mg/kg/day divided q12h Localized invasive disease: empirical therapy until susceptibility is known, then can change to oral IV: Cefotaxime 150-200 mg/kg/day divided q4-6h (max. 12 g/day) IV: Ceftriaxone 100 mg/kg/day qd or divided q12h	Antibiotics do not shorten duration of diarrheal disease. Antibiotics can prolong duration of fecal excretion. Antibiotics are recommended for infants. Treatment is initiated in children <3 months and with complications: chronic gastrointestinal disease, invasive disease (central nervous system, joint, bone, pericardium involvement), prolonged illness, bacteremia, malignant neoplasms, hemoglobinopathies, immunosuppression. Localized invasive disease: treat for total of 4 weeks (6 weeks if meningitis). Bacteremia: treat for total of 10-14 days. Drug of choice, route of administration, and duration of therapy are based on susceptibility of organisms, site of infection, host, and clinical response.
Salmonella species, typhoid	Start with IV medications; may change to oral when susceptibility is known and clinical improvement is seen Ceftriaxone 100 mg/kg/day qd or divided q12h *or* Cefotaxime 200 mg/kg/day divided q4-6h (max. 12 g/day) *or* Fluoroquinolone (>17 years or benefits outweigh risks) Ciprofloxacin 20 mg/kg/day divided q12h	Multidrug resistance is common. 10- to 14-day treatment is usually needed. Check susceptibilities.
Shigella species	IV for proven or suspected shigellosis or not able to take orals, immunosuppression, or bacteremia Ceftriaxone 50 mg/kg/dose for 5 days *or* Ciprofloxacin (>17 years or ceftriaxone contraindicated) 20 mg/kg/day divided q12h or azithromycin 10 mg/kg/day for 3 days Oral treatment (check local resistant patterns) First line: Azithromycin 12 mg/kg/day for first day, then 6 mg/kg/day for days 2-5 *or* Fluoroquinolone (>17 years or deemed necessary) Ciprofloxacin 20 mg/kg/day divided q12h for 5 days Norfloxacin 10-15 mg/kg/day for 5 days TMP-SMZ 10 mg TMP/kg/day divided q12h for 5 days *or* Ampicillin 100 mg/kg/day divided q6h for 5 days	Disease is usually self-limited, but treatment decreases diarrhea and eradicates organisms from stool. If there is no bacteremia or immunodeficiency and the child is afebrile after 2 days, two doses of ceftriaxone only may be given. Use TMP-SMZ and ampicillin only if isolated strain is susceptible because of high resistance.
Vibrio parahaemolyticus	Supportive treatment only; self-limited	
Vibrio cholerae	Oral doxycycline single dose *or* Oral tetracycline for 3 days	Antibiotics for moderately to severely ill Tetracycline is not recommended for children <8 years unless benefits outweigh risk of staining developing teeth.

www.ketabpezeshki.com 66485457-66963820

Table 173-4 Diarrheal Pathogens in Children and Specific Therapy—cont'd

	SPECIFIC THERAPY BEYOND SUPPORTIVE CARE	COMMENTS
Yersinia enterocolitica	Antibiotics for bacteremia, extraintestinal disease, immunocompromised host Oral: TMP-SMZ, 10 mg TMP/kg/day divided q12h *or* Oral or IV: Fluoroquinolone (>17 years or deemed necessary) Ciprofloxacin 20 mg/kg/day divided q12h Norfloxacin 10-15 mg/kg/day *or* IV: Ceftriaxone 50-100 mg/kg/day divided qd or q12h *or* Cefotaxime 150-200 mg/day divided q4-6h (max. 12 g/day)	Antibiotics do decrease duration of fecal excretion. Antibiotics do not decrease length of diarrhea. Isolates are usually resistant to first-generation cephalosporins and most penicillins but respond well to most aminoglycosides. Tetracycline or doxycycline (>8 years) can also be used for treatment. Extraintestinal disease: treat for 4 weeks.
Protozoa		
Cryptosporidium	Nitazoxanide for children at least 1 year of age 1-3 years: 100 mg divided q12h for 3 days 4-11 years: 200 mg divided q12h for 3 days 12 years and older: 500 mg q12h for 3 days	
Entamoeba histolytica	Asymptomatic cyst excretors Drug of choice: Iodoquinol 30-40 mg/kg/day (max. 2 g) PO divided q8h for 7 days *or* Paromomycin 25-35 mg/kg/day PO divided q8h for 7 days	
	Mild to severe intestinal disease and extraintestinal disease First line: Metronidazole 35-50 mg/kg/day divided q8h for 7-10 days *or* Tinidazole (>3 yr) 50 mg/kg/day (max. 2 g) PO daily for 3 days	For severe disease, tinidazole should be used for 5 days instead of 3 days.
	followed by luminal amebicide Iodoquinol 30-40 mg/kd/day (max. 2 g) PO divided q8h for 20 days *or* Paromomycin 25-35 mg/kg/day PO divided q8h for 7 days	Iodoquinol and paromomycin should be taken with meals.
Giardia	Metronidazole 15 mg/kg/day PO divided q8h for 5-7 days (max. 250 mg q8h) *or* Tinidazole 50 mg/kg single dose for children >3 years (max. single 2-g dose)	

Data from Pickering LK, Baker CJ, Long SS (eds): Red Book: 2009 Report of the Committee on Infectious Diseases, 28th ed. Elk Grove Village, Ill, American Academy of Pediatrics, 2009; and Custer JW, Rau RE (eds): The Harriet Lane Handbook: A Manual for Pediatric House Officers, 18th ed. Philadelphia, Mosby–Year Book, 2009.
ETEC, enterotoxigenic *E. coli*; *HUS,* hemolytic-uremic syndrome; *STEC,* Shiga-toxin producing *E. coli*. *TMP-SMZ,* trimethoprim-sulfamethoxazole.

Children 5 years and younger in daycare settings, their caregivers, and other people living in crowded conditions are at increased risk for infection. Travel to developing countries with inadequate sanitation also increases the traveler's risk for infection. Houseflies may also be vectors through transport of infected feces. The incubation period varies from 1 to 7 days. With or without antibiotics, the carrier state usually lasts about 1 week from the onset of symptoms; chronic carrier state is rare. Antibiotics are reserved for patients with prolonged symptoms, dysentery, or underlying immune compromise.[25] For this high-risk population of patients, if *Shigella* is suspected (patient with contact with a person with *Shigella* or a known regional outbreak), it is recommended that empirical treatment be started while culture and susceptibility results are awaited. According to the CDC surveillance data from 2000 to 2009, approximately 40 to 60% of isolates were resistant to ampicillin, approximately 30% were resistant to trimethoprim-sulfamethoxazole, and less than 1% were resistant to ceftriaxone and ciprofloxacin.[24] Therefore, parenteral ceftriaxone or an oral fluoroquinolone (such as ciprofloxacin or ofloxacin) could be used for 5 days in adult patients who are seriously ill. For less ill adult patients, an oral fluoroquinolone is recommended. In children, parenteral ceftriaxone for seriously ill children or oral azithromycin for less ill children is recommended. Therapy is usually recommended for 5 days. A 2-day course of ceftriaxone may be used if there is a good clinical response and no extraintestinal infection[25] (see Table 173-4).

Campylobacter species cause a significant proportion of diarrheal disease worldwide, with 2.4 million cases yearly in the United States. According to data from the CDC, there has been a 30% decline in the incidence of infection since 1996.[26] Children younger than 5 years have the highest rate of infection. It takes as few as 500 *Campylobacter* organisms to cause infection in exposed people. The organism is found in the gastrointestinal tracts and feces of fowl, farm animals, and pets. Of the five types, *C. jejuni* and *C. coli* are the most common. Illness consists of abdominal cramps, diarrhea, chills, fever, and *Shigella*-like dysentery. The clinical presentation may be similar to acute appendicitis or intussusception. Invasion of the mucosa with toxin production has been described. A 1- to 7-day incubation period is normal, and the illness usually lasts less than a week. However, approximately 20% will have a relapse or a prolonged or severe illness. Severe or prolonged disease can mimic inflammatory bowel disease. *Campylobacter* organisms are transmitted by ingestion of contaminated food (improperly cooked poultry and unpasteurized milk)

www.ketabpezeshki.com 66485457-66963820

or untreated water. Fecal-oral spread can occur, especially among very young children with diarrhea. There have been outbreaks in childcare centers, but this is rare. There has also been spread by neonates born to infected mothers that has resulted in outbreaks in nurseries. Excretion typically lasts 2 to 3 weeks without treatment. Diagnosis is made by darkfield microscopy. Oral azithromycin or erythromycin shortens the course of the illness and excretion of organisms and prevents relapse when given early (see Table 173-4). Treatment will usually eradicate the organism from the stool within 2 to 3 days. However, most children will recover without treatment.[27]

Y. enterocolitica is a relatively uncommon cause of simple self-limited diarrhea and vomiting in the United States. According to the CDC, the mean annual incidence is 0.3 per 100,000 people. However, for children younger than 5 years, the incidence is 1.9 per 100,000.[26] Infection usually is manifested with fevers and diarrhea, which may be watery, contain mucus or blood, or both. As many as 6% of older children and adults may present with an appendicitis-like illness with right lower quadrant tenderness, usually as a result of reactive mesenteric adenitis.[28] Infections usually result from eating undercooked pork or drinking unpasteurized milk. Symptoms may be prolonged, lasting 14 days or more. There have been no clinical benefits of antimicrobial therapy in the immunocompetent host with enterocolitis or mesenteric adenitis. Antibiotics are indicated for the immunocompromised with enterocolitis and in cases of septicemia and extraintestinal infections. First-line treatment of *Y. enterocolitica* infection is trimethoprim-sulfamethoxazole and aminoglycosides. Other effective antibiotics include cefotaxime, fluoroquinolones (patients 18 years or older), tetracycline, and doxycycline (patients 8 years of age or older). Isolates are often resistant to first-generation cephalosporins and most penicillins (see Table 173-4).[29]

C. difficile causes a spectrum of illnesses ranging from asymptomatic to watery diarrhea to pseudomembranous colitis. Patients usually present with diarrhea, abdominal cramps, and fever. Other common features include abdominal tenderness to palpation and dysenteric stools. Complications can include toxic megacolon and intestinal perforation. Severe disease is more common in neutropenic patients with leukemia, in infants with Hirschsprung's disease, and in patients with inflammatory bowel disease. *C. difficile* gastroenteritis most often occurs in hospitalized patients, with onset during hospitalization or within 60 days after antibiotic therapy. The organism is transmitted by fecal-oral contamination. Asymptomatic infants can be colonized with the organism; intestinal colonization in healthy neonates and young infants can be as high as 50% but usually is less than 5% in children older than 2 years. The disease is thought to be brought on by the change in the gut flora as a result of antibiotic administration. Incubation time is unknown. Pseudomembranes and friable rectal mucosa are characteristic. *C. difficile* toxin in the stool is diagnostic. In many institutions the fecal enzyme immunoassay is used for detection of toxins A and B. The results of this test are often available within hours. The sensitivity of this test is approximately 75%. Toxigenic stool culture is the most sensitive test but takes 2 to 3 days for results. Stopping the offending agent and adding therapy with oral or intravenous metronidazole or oral vancomycin for 10 days are indicated (see Table 173-4). Up to 25% of patients experience a relapse after discontinuation of therapy, but the infection usually responds to a second course with the same agent. Drugs that decrease intestinal motility should not be given.[30]

Ingested *C. perfringens* organisms produce an enterotoxin during sporulation in the gut that causes fluid collection in ileal loops and diarrhea. The result is a short-lived (usually 24 hours) illness characterized by watery diarrhea, moderate to severe abdominal cramps, and midepigastric pain. Vomiting and fever are uncommon. Food source contamination, often from catered food services (raw meat and poultry, gravies, and dried or precooked foods), is the usual source of outbreaks. The illness cannot be transferred from person to person by the fecal-oral route. The incubation time is 6 to 24 hours. The finding of high spore counts in the stool can make the diagnosis. No specific treatment is required.[31]

S. aureus produces the "typical" food poisoning from ingestion of preformed enterotoxin, usually from contaminated food. Onset of symptoms is within minutes to hours of exposure. The illness is short-lived (1-2 days) and self-limited. Abrupt and sometimes violent onset of severe nausea, vomiting, abdominal cramps, and diarrhea without fever is typical. However, low-grade fever or mild hypothermia may occur. Recovery of large numbers of bacteria or enterotoxin from stool or vomitus supports the diagnosis. Treatment is supportive. No antibiotics are indicated as the disease is self-limited.[32]

V. cholerae is an Asian-African organism that also is seen in South America. Most cases occur in travelers returning from endemic areas. A unique strain is endemic to the Gulf Coast of the United States. The disease is acquired through ingestion of contaminated water and food, such as undercooked shellfish and raw vegetables. Because a large inoculum is required, person-to-person transmission does not occur. Diarrhea is caused by a heat-labile enterotoxin that increases cAMP through adenylate cyclase, resulting in inhibition of sodium reabsorption with chloride and fluid secretion into the gut. The illness is characterized by the painless production of large amounts of watery diarrhea without abdominal cramps or fever. Dehydration, hypokalemia, metabolic acidosis, and occasionally hypovolemic shock can occur within 4 to 12 hours if fluid losses are not replaced. Antibiotic treatment should be considered for patients with moderate to severe disease—oral doxycycline as a single dose or tetracycline for 3 days in severe cholera infection. Although it is not recommended in children younger than 8 years, the benefits may outweigh the risk of staining developing teeth. It has been shown that one course of doxycycline is unlikely to cause significant tooth discoloration. Susceptibility testing is recommended because of changing resistance patterns.[33]

V. parahaemolyticus is commonly found in seawater, shellfish, and fish. Illness is most commonly associated with ingestion of contaminated raw or undercooked seafood. Diarrhea, abdominal cramps, and nausea are common, whereas vomiting, headache, fever, and chills are less common. The disease usually is self-limited and does not require treatment with antimicrobials.[33]

E. coli is part of the normal flora in the lower gastrointestinal tract. Several types within this species are recognized to cause disease. Transmission of most diarrhea caused by *E. coli* is from food or water contaminated with human or animal feces or from infected symptomatic people or carriers. *E. coli* is identified by distinct groups of either somatic or flagellar antigens that determine virulence properties. The enterotoxigenic *E. coli* (ETEC) strain produces heat-stable and heat-labile enterotoxins that affect the small intestine and cause a secretory diarrhea. It is common in infants in developing countries and in travelers of all ages. It is uncommon as a cause of diarrhea in the United States. The enteroinvasive *E. coli* (EIEC) strain is closely related antigenically and biochemically to *Shigella* species and can cause a similar dysenteric illness. It invades the large bowel epithelial cells, producing enterotoxins and colonic epithelial cell death. It can cause bloody or nonbloody diarrhea and fever in all ages. The enteropathogenic *E. coli* (EPEC) strain is responsible for sporadic and endemic diarrhea. The diarrhea is usually watery and can be severe. The illness occurs predominantly in children younger than 2 years and mainly in developing countries. It can become chronic and cause growth retardation. This form does not produce toxins. The enteroaggregative *E. coli* (EAEC) strain causes watery diarrhea in people of all ages in developing and developed countries. It has been associated with a prolonged course. The enterohemorrhagic *E. coli*

www.ketabpezeshki.com 66485457-66963820

(EHEC) strain, also known as Shiga toxin–producing *E. coli* (STEC), produces bloody diarrhea without fever; *E. coli* O157:H7 is the prototype and most virulent of the EHEC. Outbreaks have been linked to ground beef, exposure to animals in public settings (petting zoos), contaminated apple cider, raw fruits and vegetables, and ingestion of water in recreational areas. The infectious dose is low, and person-to-person transmission is common during outbreaks.[34] HUS is a serious sequel of EHEC infection.[35]

HUS consists of the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency. It typically develops in the second week of illness, often after the diarrhea has resolved. Patients often present with pallor, weakness, irritability, and oliguria or anuria. HUS occurs in up to 20% of children with *E. coli* O157:H7.[36] Approximately 50% of patients who have HUS will require dialysis, and 3 to 5% die. Patients with hemorrhagic colitis should be aggressively hydrated, admitted, and monitored closely (including complete blood cell count with smear and blood urea nitrogen [BUN] and creatinine concentrations) to detect changes suggestive of HUS. If patients have no laboratory evidence of hemolysis, thrombocytopenia, or nephropathy 3 days after resolution of diarrhea, their risk for development of HUS is low.[35]

Controversy exists about the indications for antibiotic treatment of *E. coli* diarrhea. Early data indicated that antimicrobials offer no substantial benefit and may increase the risk for development of HUS.[37] In addition, in vitro studies have shown that subinhibitory antibiotic concentrations can increase toxin production.[38] However, a subsequent meta-analysis failed to confirm the association between the use of antibiotics and the increased risk for HUS.[39] In the absence of conclusive evidence, empirical antibiotics should not be administered because of the potential risk of HUS. For severe watery diarrhea in a traveler to a developing country, azithromycin or a fluoroquinolone may be considered in an older child (>18 years).[34]

Protozoa

Protozoa can also cause diarrhea in children but are responsible for less than 1% of all cases of acute infectious diarrhea. The most common protozoa causing diarrhea are *Cryptosporidium, Giardia intestinalis,* and *Entamoeba histolytica*.

Cryptosporidium hominis is the most common of the *Cryptosporidium* species to infect humans. Children present with frequent, nonbloody, watery diarrhea. Other symptoms may include abdominal cramps, fatigue, fever, vomiting, anorexia, and weight loss. *Cryptosporidium* has been found in mammals, birds, and reptiles.[40] Outbreaks have been associated with contaminated municipal water and exposure to contaminated swimming pools. In children, the incidence is greatest during the summer and early fall. Person-to-person spread can occur and can cause outbreaks in daycare centers. In the immunocompetent child, the illness is self-limited, lasting 1 to 20 days. In the immunocompromised patient, chronic, severe diarrhea can develop and result in malnutrition, dehydration, and death. Treatment is usually supportive. However, the U.S. Food and Drug Administration has approved a 3-day course of nitazoxanide oral suspension for the treatment of immunocompetent children older than 1 year. In patients who are immunocompromised, oral administration of intravenous immune globulin is recommended.[41]

Infection with *Giardia* is limited to the small intestine and biliary tract. Children can present with intermittent watery diarrhea with abdominal pain, or they can experience protracted, intermittent, often debilitating disease characterized by foul-smelling stools with flatulence, abdominal distention, and anorexia. The disease can become chronic and can lead to weight loss, failure to thrive, and anemia. Asymptomatic infection is common. Humans are the main reservoir, although it has been found in the stool of dogs, cats, beavers, and other animals.[42] These animals can contaminate water with stool containing cysts that are infectious for humans. People contract the disease by hand-to-mouth transfer of cysts from stool of an infected person or by ingestion of fecally contaminated water or food. Epidemics from person-to-person transmission occur in childcare centers and in institutions for people with developmental delays. Duration of cyst excretion can last for months. The disease can be spread for as long as the infected person excretes cysts. Identification of trophozoites or cysts in stool specimens, duodenal fluid, or small bowel tissues by direct microscopic examination by staining methods, enzyme immunoassay, or polymerase chain reaction makes the diagnosis. An examination of a single direct smear of stool has a sensitivity of 75% and specificity of 95%. The sensitivity increases in diarrheal stools because they have a higher concentration of organisms. Looking at three or more specimens collected every other day can also increase sensitivity. Treatment includes correction of dehydration and electrolyte abnormalities and antibiotics. Tinidazole, metronidazole, and nitazoxanide are the drugs of choice (see Table 173-4). If therapy fails, a course can be repeated with the same drug. Relapse is common in the immunocompromised host, who often requires prolonged treatment. Treatment of asymptomatic carriers is not recommended except in households with hypogammaglobulinemia or cystic fibrosis.[43]

E. histolytica can be found worldwide but is more prevalent in the lower socioeconomic population and in developing countries, where the prevalence of amebic infection may be as high as 50% in some communities. Immigrants from areas with endemic infection, institutionalized people, and men who have sex with other men are at increased risk for infection. People with intestinal amebiasis often have 1 to 3 weeks of increasingly severe diarrhea progressing to grossly bloody dysenteric stools with lower abdominal pain and tenesmus. Weight loss is common, but fever occurs in less than half of the patients. Symptoms can become chronic and may mimic inflammatory bowel disease. Complications include fulminant colitis, toxic megacolon, and ulceration of the colon and perianal area, rarely with perforation. Complications are more common in patients treated inappropriately with corticosteroids or antimotility drugs. *E. histolytica* is transmitted through amebic cysts by the fecal-oral route. Ingested cysts are unaffected by gastric acid. Infected persons who are untreated can excrete cysts for years. Transmission has also been associated with contaminated food and water. Sexual transmission may also occur. Identification of trophozoites or cysts in stool specimens secures the diagnosis. Examination of serial specimens is often necessary. Enzyme immunoassay test kits are also available for routine serodiagnosis of amebiasis. Treatment of asymptomatic cyst excreters is to provide them with a luminal amebicide such as iodoquinol, paromomycin, or diloxanide (see Table 173-4). Patients with mild to moderate or severe intestinal symptoms or extraintestinal disease (liver abscess) should be treated with metronidazole or tinidazole, followed by a course of luminal amebicide. Follow-up stool examination is recommended after completion of therapy because complete eradication of intestinal infection is difficult. Asymptomatic household members with stools positive for *E. histolytica* should also be treated.[44]

Unusual Organisms in Immunosuppressed Patients

Acute infectious diarrhea in the chronically ill and immunosuppressed patient is often caused by the organisms discussed previously. However, several unusual organisms can cause diarrhea in this population of patients. In patients with acquired immunodeficiency syndrome, these infections may be acute, chronic, or recurrent and difficult to treat. Unusual organisms may include *Mycobacterium avium* and cytomegalovirus. Because of frequent antibiotic exposure, infections caused by *C. difficile,*

Box 173-1 Indications for Medical Evaluation of Children with Acute Diarrhea

Young age (e.g., <6 months or weight <8 kg)
History of premature birth, chronic medical conditions, or concurrent illness
Fever to ≥38° C for infants <3 months or ≥39° C for children 3-36 months
Visible blood in stool
High output, including frequent and substantial volumes of diarrhea
Persistent vomiting
Caregiver's report of signs consistent with dehydration (e.g., sunken eyes or decreased tears, dry mucous membranes, or decreased urine output
Change in mental status (e.g., irritability, apathy, or lethargy)
Suboptimal response to oral rehydration therapy already administered or inability of the caregiver to administer oral rehydration therapy

Modified from King CK, et al: Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. MMWR Recomm Rep 52:1, 2003.

Candida albicans, and *Pseudomonas aeruginosa* are more common in immunosuppressed patients.

Clinical Features

Diagnostic Findings

Although acute diarrhea in children often results in self-limited mild disease, it can cause significant fluid and electrolyte abnormalities that can have serious consequences. Indications for medical evaluation of children with diarrhea have been proposed (Box 173-1). Serious illnesses may be overlooked on cursory examination. The principal goals of the ED evaluation are to identify and to correct fluid, electrolyte, acid-base, and nutrient deficits that may result from vomiting, diarrhea, or decreased oral intake and to determine which children would benefit from prolonged management.

The history should include specific information about the order of presentation, duration, severity, and quantity (if applicable) for each symptom. The clinician should solicit the presence or absence of fever, nausea, vomiting, hematemesis, abdominal pain, diarrhea, and hematochezia. It is often difficult to quantify the volume of diarrhea from the history. Helping the parent describe the stool relative to usual bowel habits may provide valuable information. The consistency and content of stools are important. The relationship of symptoms to eating and drinking should be established. It is helpful to know whether other persons in the household have a similar illness and whether previous episodes have occurred. A history of travel to endemic or epidemic areas and exposure to household pets (especially turtles or reptiles) may provide important information. Quantity and time of recent oral intake and information about recent pre-illness weight can be helpful. Information about orthostatic symptoms and the patient's activity level is desirable. The past medical history should identify any chronic conditions, history of recent illnesses, rotavirus vaccination, and current medication use.

The physical examination should include close scrutiny of the vital signs while keeping in mind that clinical signs are often insensitive and nonspecific for dehydration.[45] For example, tachycardia is sensitive but nonspecific because there are many other causes of tachycardia, such as fever and anxiety. On the other hand, hypotension is specific but insensitive because children usually will maintain adequate blood pressure until severe intravascular depletion occurs. The evaluation of the child should begin with looking at the child from across the room in a position of comfort, noting the patient's overall appearance, responsiveness, activity, and work of breathing. A head-to-toe physical examination of the patient then should be performed, focusing on signs of dehydration (sunken eyes, dry mucous membranes, absence of tears, poor skin turgor, delayed capillary refill time). A general assessment of the abdomen and lungs should always be done to help rule out other pathologic processes. Clinicians often overestimate the extent of dehydration (see Table 173-5 for degree of dehydration). Clinical signs are usually not present until a child has lost at least 5% of his or her body weight. The three most useful signs in determining dehydration of more than 5% are prolonged capillary refill time, abnormal skin turgor, and abnormal respiratory pattern.[45] Older children and adults may manifest symptoms at a lesser degree of volume depletion because of relatively smaller total body water and extracellular fluid volume.

Table 173-5 Clinical Assessment of Degree of Dehydration

Older child	Mild (<3%) (30 mL/kg)	Moderate (6%) (60 mL/kg)	Severe (9%) (90 mL/kg)
Infant	Mild (<5%) (50 mL/kg)	Moderate (10%) (100 mL/kg)	Severe (15%) (150 mL/kg)
Signs and Symptoms			
Dry mucous membrane	±	+	+
Reduced skin turgor (pinch retraction)	–	±	+
Depressed anterior fontanel	–	+	+
Mental status	Alert	Irritable	Lethargic
Sunken eyeballs	–	+	+
Hyperpnea	–	±	+
Hypotension (orthostatic)	–	±	+
Increased pulse	–	+	+
Capillary refill	<2 sec	>2 sec	>2 sec
Laboratory			
Urine			
Volume	Small	Oliguria	Oliguria or anuria
Specific gravity*	≥1.020†	≥1.030	≥1.035
Blood			
BUN	WNL†	Elevated	Very high
pH (arterial)	7.40-7.30	7.30-7.10	>7.10

From Barkin RM, Rosen P: Emergency Pediatrics, 5th ed. St Louis, Mosby, 1999.
BUN, blood urea nitrogen; *WNL,* within normal limits.
*Specific gravity can provide evidence that confirms the physical assessment.
†Not usually indicated in mild or moderate dehydration.
+, present; –, absent; ± variable.

Complications

The complications of acute diarrheal illness are reflected primarily in abnormalities of fluid, electrolytes, and acid-base status and in the systemic involvement from the infection. Systemic involvement (depending on the cause of the acute diarrheal illness) may include bacteremia, osteomyelitis, polyarthritis, and HUS. Hypoglycemia and metabolic acidosis are common in younger children

www.ketabpezeshki.com 66485457-66963820

yet are manifested with nonspecific signs and symptoms. To inexperienced eyes, children may appear to compensate well, only to sometimes undergo rapid decompensation. With severe illness or illness superimposed on underlying chronic conditions, children may arrive at the ED in extremis. Children may present with weakness, lethargy, respiratory distress, shock, anuria, cardiac dysrhythmia, seizure, or coma. It is vital to recognize early signs of shock, such as persistent tachycardia, hyperpnea, irritability, and lethargy, and to restore intravascular volume before decompensation.

Diagnostic Strategies

Children who present with mild disease often require no diagnostic testing. In children assessed to have significant dehydration from acute diarrhea with or without vomiting, serum electrolyte levels and glucose concentration should be assessed. The usefulness of laboratory testing to estimate hydration status has been evaluated in multiple studies. In general, these studies concluded that laboratory tests are helpful only when results are markedly abnormal, and none alone is considered definitive for dehydration.[45-48]

Although stool culture is not indicated in most cases of uncomplicated acute gastroenteritis, stool samples should be obtained for culture if specific therapy, hospitalization, or infection control measures may be indicated. Stool cultures should also be considered in patients with systemic involvement or underlying chronic medical complications or if the illness involves dysenteric (stool with mucus, blood, or both) features. In many hospital laboratories, a routine stool culture does not include testing for *E. coli* O157:H7.[49] However, according to the CDC in 2009, all stools submitted for testing from patients with acute community-acquired diarrhea (i.e., for detection of the enteric pathogens *Salmonella, Shigella,* and *Campylobacter*) should be cultured for O157 on selective and differential agar. These stools should also be simultaneously assayed for non-O157 STEC with a test that detects the Shiga toxins or the genes encoding these toxins.[50] Therefore, for patients with suspected *E. coli* O157 infection (dysentery, diarrhea with tenesmus), one should specify to the laboratory as this culture is not routinely performed.

In immunosuppressed patients and infants younger than 3 months or children with possible bacteremia, a complete blood count, stool studies, and blood and other cultures are indicated. The stool studies of primary utility in the ED evaluation are microscopic analysis for leukocytes and occult blood to differentiate dysentery from acute gastroenteritis. Testing for fecal leukocytes is a useful initial test because it may support a diagnosis of invasive disease. This test should be considered in a febrile child with diarrhea and in a child with mucus or blood in the stool. If the test result is negative for fecal leukocytes, stool culture may not be necessary. However, if the test result is positive, stool culture is indicated. The presence of fecal leukocytes (more than five per high-power field), blood, or both indicates that the offending organism has crossed the mucosal barrier and that the risk of invasiveness has increased. Many children with acute diarrhea caused by *Salmonella* or *Shigella* organisms will have fecal leukocytes in the stool. Fecal leukocytes are also found in patients with *Campylobacter* organisms, *Y. enterocolitica,* invasive *E. coli,* and *V. parahaemolyticus*. Other studies, such as stool electrolytes, fecal fat, culture, ova, and parasites, are of greater interest and may be of help in follow-up management by the child's primary care physician.

Stool culture, enzyme-linked immunoassay for rotavirus, and other tests are indicated in patients who have not responded in the expected manner or in whom the illness is of prolonged duration (more than 2 weeks) or has dysenteric features. Additional studies also are indicated if it is necessary to identify a cause for a community outbreak. Urinalysis can provide an indication of hydration, urinary tract infection, hepatitis, and potential renal injury.

Differential Considerations

Vomiting in children is a common sign with an exhaustive list of causes. In addition to other usual causes of nausea, children may vomit in response to pain, anxiety, or fear. Some general and life-threatening causes of vomiting are presented in Table 173-1. Diarrhea also is a common reason for parents to bring their children to the ED. Most often, diarrhea is associated with other features of acute gastroenteritis, but it may be the sole presenting complaint. Table 173-2 presents a brief list of causes of diarrhea in children. An important point is that although most children with diarrhea or vomiting, or both, have a relatively benign cause of their illness, other, more sinister diagnoses should be considered and ruled out. This can often be done by careful history and physical examination.

There are some surgical diagnoses to consider in the child with diarrhea, vomiting, abdominal pain, or some combination. Appendicitis is the most common surgical condition in children and adolescents. The signs and symptoms are notoriously variable. The presence of vomiting and diarrhea does not necessarily rule out the diagnosis of appendicitis, especially when the child has abdominal pain. Intussusception is another diagnosis to consider in a young child with vomiting and abdominal pain, with or without bloody stool. The passage of currant jelly stool is often a late sign. Bilious vomiting in a child should raise concern for intestinal obstruction, such as from midgut volvulus. Enterocolitis can be the presenting manifestation as well as a subsequent serious complication of Hirschsprung's disease. HUS is a rare but potentially fatal complication of enterocolitis caused by *E. coli* O157:H7 and *Shigella*.

Management

See also the next section on dehydration.

In addition to resuscitation of children in shock, the priorities in ED management of children with diarrhea are to consider and to rule out other potential causes of diarrhea other than infectious diarrhea; to assess for and treat underlying deficits and potential complications; to determine which patients require prolonged treatment or hospitalization; and, when necessary, to arrive at a microbiologic diagnosis. Table 173-4 lists the common infectious agents of diarrhea and the indicated treatment.

Antibiotics are not needed in viral gastroenteritis or in most cases of uncomplicated bacterial gastroenteritis. Cases that may require antimicrobial therapy are those with increased potential to develop complications. This population includes those with septicemia, immunosuppression, or chronic diseases; premature babies (<1 year), neonates, and young infants; and those with articular or valve prostheses. Antibiotics are also recommended for *Giardia, Cryptosporidium,* and amebic dysentery. The child with bloody diarrhea is at higher risk for complications, including sepsis and other systemic diseases; therefore, the threshold for admission of such children to the hospital for close observation is lower. Stool cultures are indicated in the setting of acute bloody diarrhea and are helpful to guide therapy. In the majority of cases, empirical antimicrobial agents should not be administered while culture results are awaited because antimicrobial therapy might not be indicated even when culture results are positive.[51]

Antidiarrheal compounds that impair gastrointestinal motility, such as loperamide (Imodium), diphenoxylate, and atropine (Lomotil), have no role in the treatment of acute infectious diarrhea in young children. They have been shown to prolong and to

www.ketabpezeshki.com 66485457-66963820

exacerbate disease. They also have been shown to cause lethargy, paralytic ileus, toxic megacolon, central nervous system depression, coma, and even death.

There is evidence to support the use of probiotics, especially *Lactobacillus* GG (LGG), in acute infectious diarrhea in otherwise healthy infants and young children. In a randomized, double-blind, placebo-controlled trial by Szymanski and colleauges,[52] administration of LGG significantly shortened the duration of rotavirus diarrhea by a mean of 40 hours, but the duration of diarrhea of other causes was not affected. Results of other studies and a Cochrane review have indicated that probiotics reduce the number of diarrheal stools and the duration of diarrhea by approximately 1 day. These studies also reported that LGG is the most effective at doses greater than 10^{10} colony-forming units. It also appears that probiotics are more effective if they are given early in the course of the disease.[52-56] Used alongside rehydration therapy, probiotics appear to be safe and have clear beneficial effects in shortening the duration of and reducing stool frequency in acute infectious diarrhea. However, studies do not agree on the type of probiotic or dosing at this time.

Zinc deficiency is common in developing countries and occurs in most parts of Latin America, Africa, the Middle East, and south Asia. During the past 10 to 15 years, studies have shown that zinc supplementation given to children living in developing countries has decreased the duration and severity of diarrhea illness. The majority of zinc trials were conducted in countries at high risk for zinc deficiency, but those conducted at medium risk showed similar effect on duration and severity. On the basis of these findings, the World Health Organization endorses zinc supplementation for children with acute diarrhea (<6 months 10 mg/day, >6 months 20 mg/day for 10 to 14 days),[57] despite the lack of data from studies in developed countries. Currently, Children's Hospital in Boston is recruiting patients for a study on the effects of oral zinc in children with acute diarrhea in the United States.

Disposition

Most cases of childhood diarrhea can be managed on an outpatient basis by continuing routine formula or diet specific for age. Supplemental maintenance electrolyte solutions may be given. If home oral rehydration therapy is ordered, feeding should resume with an age-appropriate diet as soon as vomiting subsides. Routine fasting for diarrhea illnesses is not recommended. Before discharge from the ED, careful and specific instruction about the signs and symptoms of expected improvement or complications should be given to the parents or caregiver (Box 173-2). Instructions should address proper hygiene and handwashing techniques to prevent others from contracting the illness. Monitoring of handwashing in daycare facilities has been shown to reduce bacterial contamination in children. Follow-up by the patient's primary care physician should be timely and should address concerns of worsening of the condition and complications that may have developed. Hospitalization should be considered in children at high risk for complications: children younger than 1 year, very-low-birth-weight infants, children with chronic medical problems, children with electrolyte abnormalities who require intravenous repletion, children with severe dehydration, and children with dysentery. Hospitalization may also be warranted in cases of protracted vomiting, diarrhea with losses in excess of fluid administration, worsening clinical status despite therapy, presence of an underlying condition that would complicate therapy, or suspected systemic involvement. Very-low-birth-weight infants, because of low physiologic reserve and immature immune system, are at the highest risk for complications of acute gastroenteritis in the first year of life.

Box 173-2 Parent Instruction Sheet for Children with Vomiting and Diarrhea

Give clear liquids, as much as the child wants.
- Children younger than 2 years should be given a maintenance electrolyte solution, such as Pedialyte or Infalyte.
- Children older than 2 years may be given other clear fluids, such as decarbonated sodas, Gatorade, or clear soups.

If your child is vomiting, give clear liquids (as above) in small frequent volumes initially and advancing to normal volumes for the child's age as tolerated. It may be necessary to use teaspoons, cups, syringes, or ladles to administer the small volume. Fluid can be administered beginning 5 to 10 minutes after an episode of vomiting and should be continued despite the persistence of vomiting.

The child's diet may be advanced as soon as the vomiting has stopped and the child can tolerate fluids without vomiting. It is reasonable to wait 2 hours after the last episode of vomiting to resume feeding.
- Formula- or breast-feeding infants should be given their regular formula or returned to the breast.
- Older children should be given bland, starch-containing foods, protein, and vegetables in small quantities first and advancing to larger quantities and more complex items as the child's appetite returns.

The child may return to a regular diet as soon as the appetite returns and foods are desired.

Many foods may worsen diarrhea; pectin-containing foods, such as applesauce and other fruits and fruit juices, and foods high in fat and sugar are not recommended until the diarrhea resolves.

If cow's milk appears to cause the diarrhea to increase, reduce the amount of cow's milk products in the diet until the diarrhea has lessened significantly.

Call your child's physician or return to the emergency department if any of the following occurs:
- The diarrhea or vomiting worsens in frequency or amount.
- The vomiting lasts for more than 24 hours.
- The stool or vomitus contains blood or the vomit becomes persistently green.
- The child has decreased urine output (not as many wet diapers), does not produce tears when crying, or becomes less active or difficult to arouse.

DEHYDRATION

Clinical Features

Dehydration, or decrease in total body water, can be caused by a variety of mechanisms. Broadly speaking, however, mechanisms of dehydration represent three general categories: *decreased intake,* such as with stomatitis; *increased output,* such as with diarrhea and diabetes; and *increased insensible losses,* such as with fever. The severity of dehydration usually is measured as the acute weight (presumably fluid) loss as a percentage of pre-illness total body weight. Dehydration of more than 5% is considered significant and often can be identified by history and physical examination (see Table 173-5). Because pre-illness weights generally are not available or reliably reported, the clinician will need to rely on historical information, physical examination findings, and laboratory test results in assessing the severity of dehydration. Parental reports of history and observation are of significant value, with good sensitivity in detecting dehydration.[58] In a child who is dehydrated, initial physical examination may reveal an activity level lower than expected for age. The child may appear weak or lethargic. If the fontanel is still open, it may be sunken. The eyes appear sunken and the mucous membranes are dry (if the child has recently had something to drink, the mucous membranes may falsely appear moist). Tachycardia and hyperpnea may be present.

Table 173-7 Differential Diagnosis of Volume Depletion

FLUID LOSS CATEGORY	POTENTIAL ETIOLOGIC DISORDERS OR CONDITIONS
Renal	Diuretics, renal tubular acidosis, renal failure, urinary tract obstruction, diabetes insipidus, diabetes mellitus, hypothyroidism, adrenal insufficiency, renal trauma, salt-wasting nephritis
Extrarenal	Third spacing (pancreatitis, peritonitis, sepsis), skin loss (burns, cystic fibrosis), lung loss, congestive heart failure, liver failure, hemorrhage

Box 173-3 Principles of Appropriate Treatment of Children with Diarrhea and Dehydration

Oral rehydration solutions should be used for rehydration.
Oral rehydration should be performed as rapidly as possible.
Unrestricted diet is recommended as soon as dehydration is corrected.
For breast-fed infants, nursing should be continued.
For formula-fed infants, diluted formula is not recommended. Special formula is not necessary.
Additional oral rehydration solution should be administered for ongoing diarrheal losses.

Modified from King CK, et al: Managing acute gastroenteritis among children: Oral rehydration, maintenance, and nutritional therapy. MMWR Recomm Rep 52:1, 2003.

The skin over the trunk should be examined for tenting (suggesting hyponatremia) or a doughy texture (suggesting hypernatremia). It is important to keep in mind that clinical signs and symptoms of dehydration are variable and often subtle. The three most useful signs to determine dehydration of more than 5% are prolonged capillary refill time, abnormal skin turgor, and abnormal respiratory pattern.[45]

Laboratory tests may be helpful in assessing children for etiology, severity, and complications of dehydration. A serum electrolyte panel and BUN, serum creatinine, and blood glucose determinations are the tests most commonly ordered.[59] Sodium concentration is important in identifying isonatremic, hyponatremic, and hypernatremic states for appropriate choice of therapy (Table 173-6). A low serum HCO_3^- level may indicate loss of HCO_3^- in the stool or may reflect poor tissue perfusion. Newer noninvasive techniques for detection of dehydration have been described, such as ultrasound assessment of inferior vena cava diameter[60] and measurement of exhaled carbon dioxide as a marker for acidosis.[61] Children with dysentery should have BUN and serum creatinine concentrations measured and stool culture specimens sent and examined for *E. coli* O157:H7 to identify potential cases of HUS. Serum glucose level is important because hypoglycemia is common in young children with viral gastroenteritis, and this test may help identify children with previously undiagnosed fatty acid oxidation disorders or other inborn errors of metabolism.

Differential Considerations

Most commonly, dehydration in children results from diarrhea and vomiting caused by infectious gastroenteritis. Table 173-7 lists some other causes of dehydration that should be considered when the gastrointestinal tract is not primarily involved.

Fluid and Electrolyte Management

Oral Rehydration Therapy

Oral rehydration therapy (ORT) is a safe and effective treatment of infants and children with mild to moderate dehydration.[62-65] ORT may be instituted even if the patient continues to vomit or has diarrhea. Children with severe dehydration, shock, lethargy, acute abdomen, suspected intestinal obstruction, sodium derangement, or significant underlying illness should be identified by means of a thorough history and physical examination and laboratory tests and be excluded from ORT. Some of these principles are illustrated in Box 173-3.

The ORT period in the ED may span 4 to 8 hours and provide an opportunity to educate the family in skills of evaluating and treating childhood diarrhea. A number of ORSs have been shown to be effective. The main ingredients are water, glucose, sodium chloride, and bicarbonate in various concentrations (Table 173-8). In most situations, rehydration can be accomplished without the risk of causing hyponatremia or hypernatremia.

In infants and children with minimal dehydration, treatment should be directed at maintaining hydration and nutrition with an age-appropriate diet. Fluid intake should be increased, or ORS can be administered to cover maintenance and to replace losses. Losses can be replaced at 10 mL/kg for each stool and 2 mL/kg for each emesis. Diet should not be restricted.[62]

Children with mild to moderate dehydration should have their estimated fluid deficit replaced. The volume of ORS is calculated in the following manner:

1. Estimate the degree of volume depletion as mild or moderate with information from the history, clinical signs, and physical examination findings (see Table 173-1).
2. Calculate the desired volume of ORS as 30 to 50 mL/kg for mild (3-5%) and 60 to 80 mL/kg for moderate (6-9%) volume depletion.
3. Administer 25% of the volume of ORS to be replaced each hour for the first 4 hours.
4. Continue to replace ongoing losses as described above.
5. Monitor progress hourly and re-evaluate frequently.

This technique requires that the ED have the facilities and personnel to observe and to monitor the patient for an extended time

*May be long-chain oligosaccharide subject to hydrolysis.

to determine the success or failure of ORT. The parent or other caregiver can be taught to administer ORT. Nursing personnel also should instruct the parent in observation skills, methods of administration of the fluid, and types of fluid that are considered appropriate for children with vomiting and diarrhea. During the monitoring period, a child who is unable to tolerate intake of the prescribed volume of fluid at the expected rate should receive intravenous fluids. It is important to determine whether the failure is the result of the child's inability to ingest the fluid, excessive fluid loss through vomiting or diarrhea, or poor technique or motivation on the parent's part. It usually is possible to maintain the fluid administration rate in children who continue to vomit by administering small volumes frequently. This may require, for instance, use of a spoon or syringe to slowly drip the fluid by hand. Some success has been obtained with the use of nasogastric tubes.[66]

The patient is reassessed at the end of the first few hours. If the clinical examination indicates adequate volume repletion, the child may be discharged home with further specific instructions for parents about maintenance fluid requirements with ORS. If, on the other hand, the child still exhibits mild or moderate volume depletion on clinical examination but no deterioration in status has occurred, the child is reevaluated as if from the beginning, and another 2- to 4-hour trial is attempted. If the child is unable to ingest the appropriate volume to keep up with ongoing losses or if volume repletion is not achieved at the end of 8 hours, intravenous therapy and admission should be initiated.

In the last several years, ondansetron has become a useful adjunct in the treatment of acute gastroenteritis in the pediatric ED. Ondansetron, a selective 5-hydroxytryptamine type 3 receptor antagonist, acts at chemoreceptors in the peripheral and central nervous system to alleviate nausea, which has been shown in numerous well-designed studies in children to reduce episodes of vomiting in the pediatric ED, to reduce the need for intravenous fluid rehydration, and to improve oral intake in the pediatric ED.[67-71]

Intravenous Therapy

Some dehydrated children brought to the ED may not qualify for ORT, and others may fail to improve with ORT. These patients include those with shock, severe dehydration, increasing deficit or clinical deterioration during ORT, intractable vomiting, hypoglycemia, or electrolyte derangements.

Patients are evaluated in accordance with their immediate (emergency phase, phase I), short-term (repletion phase, phase II), and long-term (early refeeding phase, phase III) needs.[72] During the *emergency* phase, the aim of fluid resuscitation is to restore circulatory volume. This fluid needs to be administered rapidly to prevent imminent serious morbidity or death. During the *repletion* phase, fluid and electrolyte derangements are reversed, and ongoing losses are replaced. This phase lasts 24 hours. In the *early refeeding* phase, long-term needs are addressed in the next few days, during which the body recovers fluid, electrolyte, and nutritional homeostasis. Immediate and short-term therapies are initiated in the ED, with subsequent phases carried out in the inpatient setting or at home as managed by the primary care physician. In clinical practice, this algorithm represents a continuum of care and not three distinct, separate phases. Monitoring of serum electrolyte, BUN, and blood glucose concentrations is indicated for patients receiving intravenous fluid therapy.

Emergency Resuscitation Phase.[72] Rapid reexpansion of the intravascular space is the goal of immediate resuscitation and can be achieved with an isotonic crystalloid solution. Administration of 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) intravenously at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. In critical situations, intraosseous routes should be used if venous access is not immediately available. Subcutaneous administration may be considered in resource-limited areas of the world as an alternative for rehydration when oral rehydration is not successful. Patients should be reevaluated periodically, and those with excessive deficits should receive repeated boluses of 20 mL/kg until clinical improvement occurs. Signs of recovery include normalization of blood pressure measurements, improvement of mental status, improvement of tachycardia and capillary refill time, and production of urine. Volume requirements greater than 60 mL/kg without signs of improvement warrant investigation for other conditions, such as septic shock, hemorrhage, capillary leak with third-space fluid sequestration, congestive heart failure, and toxic shock.

A rapid determination of serum glucose is important. Children require glucose as an energy substrate and often have marginal stores available in illnesses. If the serum glucose concentration is low (<50 mg/dL), dextrose 0.25 to 0.5 g/kg should be rapidly administered intravenously or intraosseously. For neonates, a D10 solution is used, and approximately 4 mL/kg is given. For children 1 month of age to approximately 8 years or 25 kg, 2 mL/kg of D25

www.ketabpezeshki.com 66485457-66963820

is given. In children older than 2 years, 1 mL/kg of D50 can be used. Glucose levels should be monitored (every 30 to 60 minutes until stable) to ensure improvement and to identify ongoing needs. Repeated episodes of hypoglycemia should raise concern for sepsis, fatty acid oxidation defects, and other inborn errors of metabolism.

Repletion Phase.[72] After immediate resuscitation, appropriate fluid therapy for the patient should be determined. Some patients may return to ORT after initial resuscitation. Calculations should take into account the fluids already administered and maintenance fluid (Table 173-9), and they should also accommodate changes in the patient's clinical status. To allow accurate planning of the type and amount of fluid to be administered, volume replacement should proceed from the serum sodium level: hypernatremia (>150 mEq/L), hyponatremia (<130 mEq/L), or isonatremia (130-150 mEq/L).

Isonatremic Volume Depletion.[72] Isonatremic volume depletion is the most common form of volume depletion and results from relatively equal losses of sodium and water. No change in body fluid tonicity or redistribution of fluid between the extracellular and intracellular fluid spaces occurs. This results in loss of fluid from the extracellular space and therefore intravascular volume depletion. Gastrointestinal fluid loss with or without decreased intake or increased urine loss is the most common cause. Repletion fluids are outlined for a sample patient in Box 173-4. In general, with use of 5% dextrose in 0.45% sodium chloride, half of the deficit fluids is given during the first 8 hours of repletion along with maintenance fluids. Potassium may be added to maintenance fluids once urine output is established and serum potassium levels are within a normal range. Continued losses (emesis, diarrhea) should also be replaced.

Table 173-9 Maintenance Fluid and Electrolytes

BODY WEIGHT	WATER mL/kg/day	WATER mL/kg/hr	ELECTROLYTES mEq/100 mL H_2O
First 10 kg	100	4	Na^+ 3
Second 10 kg	50	2	Cl^- 2
Each additional kg	20	1	K^+ 2

Box 173-4 Sample Calculation of Fluid and Electrolyte Requirements in a Patient with Isonatremic Volume Depletion

Isonatremic Volume Depletion: Management of Moderate to Severe Deficits

Initial Findings

Pre-illness weight: 10 kg (a 1-year-old)
Degree of volume depletion: moderate (10%)
Body weight on admission: 9 kg
Electrolytes: Na^+ 135 mEq/L, K^+ 5 mEq/L, Cl^- 115 mEq/L, HCO_3^- 12 mEq/L

Summary of Fluid Requirements

	H_2O (mL)	Na^+ (mEq)	K^+ (mEq)
Maintenance	1000 (100 mL/kg)	30 (3 mEq/kg)	20 (2 mEq/kg)
Deficit (100 mL/kg)*			
ECF (60%)	600	84 (140 mEq × 0.6)	
ICF (40%)	400		30 (150 mEq × 0.4 × 50% correction)
TOTAL	1000 mL	84 mEq	30 mEq
Resuscitation fluids	200 mL	28 mEq	
Net deficit	800 mL	56 mEq	30 mEq

Na^+ extracellular fluid (ECF) concentration = 140 mEq/L.
K^+ intracellular fluid (ICF) concentration = 150 mEq/L.

Fluid Schedule

Phase	Calculation	Fluids Administered
I (0-½ hr)	20 mL/kg	200 mL 0.9% NS or LR during 20-30 minutes
II (½-9 hr)	½ net deficit: 400 mL D_5W with 28 mEq NaCl and 15 mEq KCl ⅓ maintenance: 333 mL D_5W with 10 mEq NaCl and 7 mEq KCl TOTAL: 733 mL with 38 mEq NaCl and 22 mEq KCl	733 mL (~90 mL/hr) of D_5W/0.45% NS with 22 mEq KCl (~30 mEq/L) (this approximation facilitates care)
III (9-25 hr)	½ deficit ⅔ maintenance	1067 mL (~67 mL/hr) of D_5W/0.45% NS with 28 mEq KCl (~26 mEq/L) (this approximation facilitates care)

Notes

1. Fluid resuscitation is crucial during phase I. If initial response is poor, additional infusions are warranted. In general, the initial emergency fluid bolus should be included as part of the deficit replacement.
2. Blood glucose concentration should be assessed early, especially in children with prolonged vomiting, diarrhea, or inadequate intake. Early glucose infusion may be warranted.
3. In the face of acidosis, serum potassium concentration does not reflect total body deficit.
4. Adjust for fever (add 10% for each 1° C above 37° C), stool loss (5 mL/kg), or vomiting (volume for volume).

Modified from Barkin RM, Rosen P (eds): Emergency Pediatrics, 5th ed. St Louis, Mosby, 1999; and Custer JW, Rau RE (eds): The Harriet Lane Handbook: A Manual for Pediatric House Officers, 18th ed. Philadelphia, Mosby–Year Book, 2009.
*Deficit = % dehydration × weight (kg) × 1000 mL/kg.

Box 173-5 Sample Calculation of Fluid and Electrolyte Requirements in a Patient with Hyponatremic Volume Depletion

Hypotonic Volume Depletion: Management of Moderate to Severe Deficits

Initial Findings

Pre-illness weight: 10 kg (a 1-year-old)
Degree of volume depletion: moderate (10%)
Body weight on admission: 9 kg
Electrolytes: Na^+ 110 mEq/L, K^+ 5 mEq/L, Cl^- 90 mEq/L, HCO_3^- 12 mEq/L

Summary of Fluid Requirements

	H_2O (mL)	Na^+ (mEq)	K^+ (mEq)
Maintenance	1000 (100 mL/kg)	30 (3 mEq/kg)	20 (2 mEq/kg)
Deficit (100 mL/kg)			
ECF (60%)	600	84 (140 mEq × 0.6)	
ICF (40%)	400		30 (150 mEq × 0.4 × 50% correction)
Sodium deficit*		125	
TOTAL	1000 mL	209 mEq	30 mEq
Resuscitation fluids	200 mL	28 mEq	
Net deficit	800 mL	181 mEq	30 mEq

Fluid Schedule

	Fluids	
Phase	**Calculation**	**Administered**
I (0-½ hr)	20 mL/kg	200 mL 0.9% NS or LR during 20-30 minutes
II (½- 9 hr)	½ net deficit: 400 mL D_5W with 90 mEq NaCl and 15 mEq KCl ⅓ maintenance: 333 mL D_5W with 10 mEq NaCl and 7 mEq KCl TOTAL: 733 mL with 100 mEq NaCl and 22 mEq KCl	733 mL (~90 mL/hr) of D_5W/0.9% NS with 22 mEq KCl (~30 mEq/L) (this approximation facilitates care)
III (9-25 hr)	½ deficit ⅔ maintenance	1067 mL (~67 mL/hr) of D_5W/0.9% NS with 28 mEq KCl (~26 mEq/L) (this approximation facilitates care)

*Sodium Deficit Calculation

A. Na^+ required to correct to 135 mEq/L = 135 mEq/L – 110 mEq/L (observed Na^+) = 25 mEq/L
B. Total body water (TBW) (L/kg) = 0.6 L/kg (pre-illness TBW) – 0.1 L/kg (water loss) = 0.5 L/kg
C. Pre-illness weight = 10 kg
Sodium deficit = A × B × C = 25 mEq/L × 0.5 L/kg × 10 kg = 125 mEq

Notes

1. Fluid resuscitation is crucial during phase I. If initial response is poor, additional infusions are warranted. In general, the initial emergency fluid bolus should be included as part of the deficit replacement.
2. In the face of severe hyponatremia with decreased total body water in symptomatic patients, hypertonic 3% saline must be given to raise the serum sodium level to 125 mEq/L. A 3% saline solution contains approximately 0.5 mEq/mL of Na^+. Patients may be given 3% saline 4 mL/kg intravenously during 10 minutes and the response monitored. Once seizures have stopped, half of the deficit may be corrected during the next 8 hours as outlined in the fluid schedule.
3. If excess water load is the cause, furosemide (Lasix) 1 mg/kg/dose intravenously may be used. During the subsequent diuresis, urinary sodium, potassium, and chloride should be measured and replaced milliequivalent for milliequivalent with 3% saline and supplemental potassium chloride.
4. Blood glucose concentration should be assessed early, especially in children with prolonged vomiting, diarrhea, or inadequate intake. Early glucose infusion may be warranted.
5. In the face of acidosis, serum potassium concentration does not reflect total body deficit.
6. Adjust for fever (add 10% for each 1° C above 37° C), stool loss (5 mL/kg), or vomiting (volume for volume).

Modified from Barkin RM, Rosen P (eds): Emergency Pediatrics, 5th ed. St Louis, Mosby, 1999; and Custer JW, Rau RE (eds): The Harriet Lane Handbook: A Manual for Pediatric House Officers, 18th ed. Philadelphia, Mosby–Year Book, 2009.
D_5W, 5% dextrose in water; *ECF,* extracellular fluid; *ICF,* intracellular fluid; *NS,* normal saline; *LR,* lactated Ringer's solution.

Note that the sample patient is mildly acidemic ($HCO_3^- >$ 12 mEq/L) and that restoration of intravascular volume results in improved tissue perfusion and correction of the metabolic acidosis. These calculations account for water and electrolyte requirements (maintenance and deficit) and demonstrate that use of a standard fluid preparation (0.9%, 0.45%, or 0.2% saline) permits close approximation of calculated requirements and facilitates treatment by relying on readily stocked supplies.

Hyponatremic Volume Depletion.[72] Hyponatremic volume depletion is a result of loss of relatively more sodium than water, resulting in extracellular water shift into the intracellular fluid space to maintain equal osmolarity. This results in a significant decrease in intravascular volume and hemodynamic compromise. This type of volume depletion usually is caused by gastrointestinal fluid loss that has been replaced with hypotonic fluid. Specific signs and symptoms of hyponatremia are largely neurologic, ranging in severity from malaise and irritability to seizures and coma.

Appropriate management of hyponatremic dehydration for a sample patient is described in Box 173-5. If the serum sodium concentration is 120 to 130 mEq/L, 5% dextrose in 0.9% saline is administered, with half of the daily fluid requirement given in the first 8 hours and the remainder during the succeeding 16 hours. Monitoring of serum electrolyte values, BUN level, weight, and intake and output is recommended. Rapid correction of hyponatremia can be associated with central pontine myelinolysis. Close

www.ketabpezeshki.com 66485457-66963820

monitoring of serum sodium concentration is indicated, and the amount of sodium in the fluid is adjusted to maintain a slow correction. The target rate of rise of sodium is 2 to 4 mEq/L every 4 hours or 10 to 20 mEq/L in 24 hours.[72] Potassium chloride, 20 mEq/L, is added to the intravenous fluids after renal function is assessed and urine output has been established. If the serum sodium concentration is less than 120 mEq/dL, the patient may exhibit seizures, hyperexcitability, or other neurologic symptoms. In such cases, 3% saline (sodium chloride 0.5 mEq/mL) should be administered as a bolus dose of 4 mL/kg. This dose will raise the serum sodium concentration by 3 to 4 mEq/L.

Hyponatremic dehydration should be differentiated from another common cause of hyponatremia, the syndrome of inappropriate antidiuretic hormone secretion (SIADH). In this syndrome, caused by a variety of conditions, the kidneys inappropriately excrete sodium and retain water, resulting in low serum sodium and high urinary sodium concentrations. Initial treatment is with fluid restriction.

Hypernatremic Volume Depletion.[72] Hypernatremic volume depletion (serum sodium level >150 mEq/L) arises with loss of relatively more water than sodium. It can occur if inappropriate types of fluids are given, if the fluid or formula is mixed incorrectly, or if fever or hyperventilation complicates the illness. This is the least common type of volume depletion because of a generally lower content of sodium in most modern infant fluids and formulas. Intracellular water shifts to the extracellular fluid space to maintain osmolar balance; therefore, intravascular volume is relatively preserved. Signs and symptoms specific to hypernatremia are doughy skin and altered central nervous system function (manifested as irritability, seizures, or high-pitched cry). Care should be taken not to administer hypotonic fluid at too fast a rate because water will equilibrate across the cerebral blood-brain barrier almost immediately (long before the sodium concentration is corrected), creating increased intracranial pressure. The most important goal is to reestablish intravascular volume and return serum sodium levels toward normal gradually (48-72 hours). After adequate volume expansion, rehydration fluids should be initiated with 5% dextrose in 0.2% to 0.45% sodium chloride at a slow rate during 48 to 72 hours. Serum sodium levels should be assessed every 4 hours. The goal is to reduce the serum sodium level at a rate of 0.5 to 1 mEq/L per hour.[73] If the sodium level has decreased by less than 0.5 mEq/L per hour, sodium content of the rehydration fluid is decreased. This will allow a slow controlled correction of the hypernatremia. Box 173-6 provides guidelines for the calculation of fluids and electrolytes for a sample case. Close monitoring of neurologic status and serum electrolyte levels is important during the period of rehydration. It is imperative to remember to replace ongoing losses.

Hospital-Acquired Hyponatremia. One of the complications that can develop during intravenous rehydration in children is acute hyponatremia. In children, this rare disturbance can lead to significant neurologic morbidity, including seizures, coma, and brain herniation or even death. For acute hyponatremia to occur, two conditions have to be met: (1) an exogenous source of free water must be available, and (2) secretion of antidiuretic hormone must occur. Many experts therefore recommend use of isotonic saline rather than hypotonic saline as the replacement intravenous fluid of choice in hospitalized children.[74,75] This practice is not universally accepted.[76] In any case, vigilance in monitoring of the neurologic status of children undergoing intravenous rehydration is essential.

Box 173-6 Hypertonic Dehydration

A 2-week-old infant presents to the emergency department with a history of 1 day of poor breast milk intake. Weight yesterday at a well-baby visit was 4 kg; today the child weighs 3.4 kg. Laboratory study findings include serum Na^+ 155 mEq/L, K^+ 4.5 mEq/L, and HCO_3^- 13 mEq/L.

Maintenance Therapy

100 mL/day for first 10 kg = 400 mL
Na^+ requirements = 3 mEq/kg × 4 kg = 12 mEq
K^+ requirements = 2 mEq/kg × 4 kg = 8 mEq

Total Fluid Deficit: 4.0 – 3.4 = 0.6 L

Free water deficits = observed Na^+ – ideal Na^+ (145 mEq/L) × 4 mL/kg × wt (kg) = (155 – 145) × 4 mL/kg × 4 kg = 160 mL

Na^+ Deficit

The illness is less than 3 days in duration. Therefore, the fluid lost is 75% from the ECF and 25% of the ICF. The primary sodium reservoir is the ECF.

$$\begin{aligned} Na^+ \text{ loss} &= (\text{ECF } Na^+ \text{ concentration}) \\ &\quad \times (75\% \text{ of solute fluid deficit*}) \\ &= (140\ \text{mEq/L}) \times (0.75 \times 0.440\ \text{L}) \\ &= 46\ \text{mEq} \end{aligned}$$

NOTE: Solute containing deficit:
Total fluid deficit – free water deficit = 600 mL – 160 mL = 440 mL

K^+ Deficit (Primary Potassium Reservoir is ICF)

$$\begin{aligned} K^+ \text{ loss} &= (\text{ICF } K^+ \text{ concentration}) \\ &\quad \times (25\% \text{ of solute fluid deficit}) \\ &= (150\ \text{mEq/L}) \times (0.25) \times 0.440\ \text{L} \\ &= 16\ \text{mEq} \end{aligned}$$

48-Hour Requirements = Maintenance + Deficits

Total deficits:
Fluid (mL) = (400 × 2) mL + 160 mL (free) + 440 mL (solute) = 1400 mL
Sodium (mEq) = 24 + 46 = 70 mEq
Potassium (mEq) = 16 + 16 = 32 mEq

Fluid Schedule

The fluid is administered in a stepwise fashion during 48 hours. Half of the deficit is given in the first 24 hours; then the remainder is given during the next 24 hours.

First Day Fluids = Maintenance + ½ Deficits

First day fluids = (400 mL + 12 mEq Na^+ + 8 mEq K^+) + ½(600 mL + 46 mEq Na^+ + 16 mEq K^+)
First day fluids = 700 mL D_5W + 35 mEq Na^+ + 16 mEq K^+

In practice (and after the calculations are done), the usual fluid that is required to rehydrate the child with hypertonic dehydration is either D_5W/0.2% NS or D_5W/0.45% NS because it would appear that the *rate* rather than the type of fluid is most important. The volume of free water needed to lower a serum sodium concentration above 145 mEq/L is approximately 4 mL/kg of free water for each 1 mEq/L during 48 hours. Studies demonstrate that D_5W, D_5W/0.2% NS, and D_5W/0.45% NS are acceptable if the fluid is infused at a conservative rate, correcting deficits during 48 hours.

Modified from Barkin R, et al: Pediatric Emergency Medicine, 2nd ed. St Louis, Mosby, 1997.
D_5W, 5% dextrose in water; *ECF*, extracellular fluid; *ICF*, intracellular fluid; *NS*, normal saline.
*Calculated as (600 mL fluid deficit – 160 mL free water deficit).

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

Identification of Pathogen

- Stool studies are not indicated in most uncomplicated cases of acute gastroenteritis. Exceptions are those cases in which specific treatment, specific prophylaxis, or health precautions are required or in which the patient has systemic involvement or underlying medical complications or the illness involves dysenteric features.

Fecal Leukocytes

- Testing for fecal leukocytes is a useful initial test because it may support a diagnosis of invasive disease. This test should be considered in a febrile child with diarrhea and in a child with mucus or blood in the stool. If the test result is negative, stool culture may not be necessary. If the test result is positive, stool culture is indicated. The presence of fecal leukocytes (more than five per high-power field), blood, or both indicates that the offending organism has crossed the mucosal barrier and that the risk of invasiveness has increased. Nearly 90% of patients with acute diarrhea caused by *Salmonella* or *Shigella* organisms will have fecal leukocytes in the stool.

Oral Rehydration

- Most patients with mild to moderate dehydration can be treated with ORT. With ORT, resumption of feeding with age-appropriate diet should begin as soon as vomiting subsides. Routine fasting with infectious diarrhea is not recommended.

Dehydration Assessment

- The degree of volume depletion is estimated by information from the history, clinical signs, and physical examination findings. The desired volume of oral rehydration solution (ORS) is calculated as 30 to 50 mL/kg for mild and 60 to 80 mL/kg for moderate volume depletion; then 25% of the volume of ORS is to be replaced every hour (100% during 4 hours).

Severe Dehydration

- In severe dehydration, 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) given intravenously at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. Repeated boluses of 20 mL/kg are indicated until clinical improvement occurs, but volume requirements greater than 60 mL/kg without signs of improvement suggest other conditions, such as septic shock, hemorrhage, capillary leak with third-space fluid sequestration, and heart failure.

CHAPTER 174

Genitourinary and Renal Tract Disorders

Maureen McCollough and Ghazala Q. Sharieff

PERSPECTIVE

This chapter discusses some of the more common causes of scrotal, testicular, and penile pain in children that precipitate a visit to the emergency department (ED). Also discussed are other renal or genitourinary tract disorders in this age group for which emergent treatment may be sought, including acute renal failure, urinary tract infections, and hypertension.

SPECIFIC DISORDERS

Penile Disorders

Priapism

Principles of Disease. Priapism is the engorgement of the dorsal corpora cavernosa, resulting in dorsal penile erection and ventral penile flaccidity. The more common low-flow priapism is secondary to decreased venous outflow and is characterized by prolonged painful erection. Sickle cell disease and leukemia are responsible for the majority of cases in children. Immunosuppressive disorders, anticoagulation, and intracavernosal injection of agents such as papaverine, phentolamine, and prostaglandin E_1 also can result in priapism. Other drugs, such as phenothiazines, sedative-hypnotics, selective serotonin reuptake inhibitors, antihypertensives, anticoagulants, and drugs of abuse (e.g., cocaine, alcohol, marijuana), may be causal. Priapism complications include penile fibrosis, urinary retention, and impotence.

High-flow priapism usually is painless and typically is associated with penile arterial laceration and excessive inflow of arterial blood or spinal trauma resulting in corporal engorgement. With prolonged engorgement of the corpora cavernosa, the resultant stagnation and hypoxia of the blood lead to the development of thrombosis and ischemia.

Clinical Features. Priapism is a clinical diagnosis and can be distinguished from other causes of erection by careful history and complete physical examination. The history should include past medical history with attention to previous treatment of anemia, leukemia, sickle cell disease, or drug abuse and current history of trauma or symptoms of immunosuppressive disease. Although priapism is a clinical diagnosis, laboratory studies may assist in isolation of the cause of the condition. A complete blood count (CBC), urinalysis, and coagulation studies may be useful in some cases. Diagnostic studies of penile blood flow may be indicated in cases for which the cause is unclear. Studies that the urologist may request include magnetic resonance imaging, color Doppler cavernosography, and technetium Tc-99m penile scanning. Angiography is helpful in localization of the arterial bleeding site in high-flow priapism.

Differential Considerations. The differential diagnosis for priapism in children differs from that in adults. In adults, penile erection from sexual arousal, urethral foreign bodies, Peyronie's disease, spinal cord injury, and penile implants may occur, but these etiologic factors are rare in children. Anticoagulation, drugs of abuse, medications, trauma (including spinal trauma), Kawasaki disease, leukemia, and sickle cell disease are associated with priapism in children.

Management and Disposition. Management centers on hydration, pain control, relief of urinary obstruction, and treatment of any other underlying conditions. Local anesthesia by a dorsal nerve block with 1% lidocaine without epinephrine may be beneficial. In patients with sickle cell disease, treatment with oxygen, hydration at 1.5 times maintenance volume, and analgesics should be initiated. Low-flow priapism may respond to sitz baths or hot compresses because the heat increases blood flow, thereby potentially relieving the obstruction. Oral terbutaline (adult dose 5-10 mg, followed by another 5-10 mg 15 minutes later) produces resolution in about one third of patients. If no resolution occurs within 30 minutes of treatment, aspiration and irrigation therapy is required.

Cavernosal aspiration plus irrigation has been effective in patients with low-flow priapism. This procedure should be performed within the first few hours of symptom onset and rarely is beneficial after 48 hours. Vasoactive substances such as phentolamine and phenylephrine may be used for irrigation therapy; however, these are best administered with urologic consultation. Parenteral vasodilators, such as methylene blue, hydralazine, and terbutaline, also have been tried with variable success, and therefore the treating urologist can help ascertain the best treatment approach.[1-4]

Exchange transfusion for patients with priapism and sickle cell disease previously has been recommended; however, this treatment may not offer any advantage over conventional therapy and has been associated with serious neurologic sequelae, as in the so-called ASPEN syndrome (*a*ssociation of *s*ickle cell disease, *p*riapism, *e*xchange transfusion, and *n*eurologic events).[2,3] Patients with leukemia may respond with detumescence after chemotherapy is begun.

High-flow priapism can be effectively addressed by arterial embolization. Studies have shown success with the use of autologous blood clot embolization.[4]

If nonsurgical approaches are unsuccessful, referral to a urologist for a corpus cavernosum–glans shunt procedure may be necessary. Ultrasound-guided compression of the perineal arteriocavernous fistula has been successful.[5] Interventions should be initiated within 12 hours of symptom onset to avoid long-term dysfunction and irreversible infarction.[6] Patients with persistent priapism or underlying disorders, such as leukemia or sickle cell

www.ketabpezeshki.com 66485457-66963820

disease, may require hospitalization. Pediatric urologic consultation should be arranged as soon as possible. If the priapism has been treated successfully, the patient may be discharged home after some period of observation with urologic specialist follow-up.

Phimosis

Principles of Disease. Phimosis is a pathologic condition of the uncircumcised penis in which constriction of the foreskin prevents retraction of the prepuce from the glans. It can result in pain, hematuria, glans ischemia, infarction, and urinary outlet obstruction. Most cases are physiologic, representing normal development, and do not require intervention. Only 4% of newborn boys have a fully retractable foreskin. This percentage increases with age: 25% of 6-month-old, 50% of 1-year-old, 80% of 2-year-old, and 90% of 4-year-old boys have fully retractable foreskins.[7] Phimosis also may result from trauma, infections, chemical irritation, poor hygiene, and congenital abnormality or be a complication of circumcision.

Clinical Features. Phimosis is a clinical diagnosis. History may reveal that the foreskin is unretractable, along with narrowing or diversion of the urinary stream and bulging out of the foreskin with urination. Pain and hematuria may be accompanying features.

Management and Disposition. Because the ability to retract the foreskin fully is age related, parents should be advised not to retract the prepuce forcefully. Gentle retraction with good hygiene should be stressed. If signs of urinary outlet obstruction are present, dilation of the prepuce or the urethral meatus or both can be performed by gentle use of forceps. With vascular compromise of the glans, a dorsal split procedure, circumcision, preputial plasty, or balloon dilation may be necessary.[8,9] Topical steroid treatment (with betamethasone valerate 0.6% cream) for 6 weeks has been 87% effective in reducing inflammation and treating phimosis.[10-12] In patients with severe stenosis, obstructive uropathy can result. In such rare cases, blood urea nitrogen (BUN) and serum creatinine levels should be obtained, and a renal ultrasound examination should be performed if signs of obstructive renal failure are present. Patients who are able to urinate and have no evidence of severe infection or ischemia can be discharged from the ED with outpatient urologic follow-up.

Figure 174-1. Paraphimosis in a 4-year-old uncircumcised boy. (Courtesy Marianne Gausche-Hill, MD.)

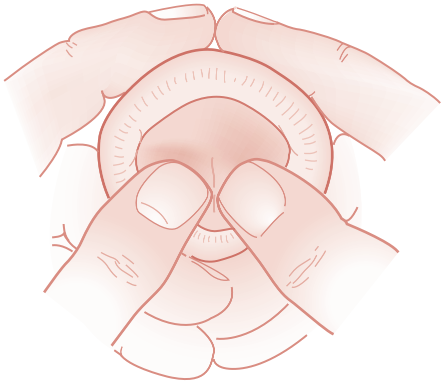

Figure 174-2. Paraphimosis reduction. (Courtesy P. P. Kelalis.)

Paraphimosis

Principles of Disease. Paraphimosis is another pathologic condition of the uncircumcised penis in which the proximal foreskin cannot be returned to its anatomic position covering the glans penis, resulting in distal venous congestion with the potential for dire consequences. Paraphimosis can be caused by infection, masturbation, trauma, or hair or clothing tourniquets. Iatrogenic causes include failure to reduce the foreskin after a medical examination. Paraphimosis constitutes a true urologic emergency and can result in arterial compression, penile necrosis, and gangrene.

Clinical Features. The patient typically is anxious, and the history often reveals that the parents or the patient retracted the foreskin and then could not replace the foreskin over the glans (Fig. 174-1). The history should include verification that the patient is uncircumcised because hair tourniquet syndrome in a circumcised patient may mimic paraphimosis. Physical examination reveals a flaccid proximal penis with erythema and engorgement distal to the obstruction. The foreskin is retracted, and cellulitis may be present. The diagnosis of paraphimosis is based on clinical findings, but if a penile foreign body is a concern, radiographs can be obtained after relief of the vascular occlusion.

Management and Disposition. Pain can be controlled either parenterally or by a local dorsal penile nerve block. Procedural sedation also may be necessary. Placement of a finger of a rubber glove filled with ice water over the glans and foreskin can reduce the edema. Circumferential compression of the penis starting at the glans also can reduce the edema. Compression may need to be held for several minutes to achieve adequate reduction of edema. Manual reduction may be necessary, with application of gentle, steady pressure on the glans with both thumbs while the shaft is pulled straight (Fig. 174-2). Another method is to puncture the edematous foreskin with an 18- or 21-gauge needle.[13,14] The puncture may be followed by squeezing of the glans penis to further facilitate fluid drainage. Dorsal band traction has been performed in some cases with Adson forceps applied directly to the band formed by the retracted foreskin and application of traction and countertraction to loosen the constriction. If all such attempts fail, urologic consultation proceeding to circumcision or a dorsal slit procedure may be necessary. Patients can be discharged home after reduction if they are able to void spontaneously and urologic follow-up care can be arranged. Any evidence of cellulitis or necrosis warrants hospital admission, intravenous antibiotics, and urologic consultation.

Balanoposthitis

Principles of Disease. Balanoposthitis, an inflammation that involves the glans and the foreskin, occurs in up to 6% of

www.ketabpezeshki.com 66485457-66963820

Figure 174-3. Balanoposthitis in an 8-month-old boy caused by candidal infection. (Courtesy Marianne Gausche-Hill, MD.)

uncircumcised males.[15] Balanitis involves the glans penis only. The primary cause of balanoposthitis is infection; however, chemical irritation, trauma, fixed drug rash, and contact dermatitis also can be contributory. Infectious organisms are gram negative and gram positive, including group A beta-hemolytic streptococci and rarely *Neisseria gonorrhoeae* and *Chlamydia*.[16] Recurrent episodes of *Candida albicans* balanoposthitis should raise suspicion for diabetes mellitus.

Clinical Features. Physical examination reveals penile erythema, edema, and possibly a discharge (Fig. 174-3). Systemic symptoms and signs such as fever, vomiting, and diarrhea are unusual. Diagnosis is clinical and treatment is based on clinical findings; however, if symptoms are severe, the offending organism can be identified by culture of any discharge.

Management and Disposition. Management includes emphasis on adequate hygiene with sitz baths to reduce inflammation. Painful micturition can be addressed by having the child urinate while in a bath of warm water. In patients with cellulitis, antibiotic treatment with agents effective against *Staphylococcus aureus* and *Streptococcus pyogenes* is recommended. Seven days of a first-generation cephalosporin is an appropriate regimen. If group A beta-hemolytic streptococci are identified, a streptococcus-specific antibiotic is required.[17] Severe inflammation may be treated with 0.5% hydrocortisone cream applied sparingly to the area. Candidal infections should be treated topically with antifungals. A blood glucose determination should be considered in patients presenting with recurrent candidal balanoposthitis. Patients with a toxic appearance or those who exhibit evidence of cellulitis or constricting phimosis with uropathy should be hospitalized for appropriate management. Circumcision may be required for patients with recurrent disease.

Complications of Circumcision

Principles of Disease. Although there remains societal controversy about circumcision, it is usually advocated for prevention of phimosis, paraphimosis, recurrent balanoposthitis, urinary tract infections, and penile cancer. Any of three techniques can be used: application of a Plastibell or Gomco clamp, excision, or dorsal slit procedure. The choice of procedure depends on the preference of the operator. The most common complication of these procedures is hemorrhage, which usually is minor and can be controlled by direct pressure, silver nitrate application, or suture placement. Significant bleeding may be a sign of a blood dyscrasia. Localized, systemic, or urinary tract infection also can occur.

Management and Disposition. Postoperative pain usually resolves within 12 to 24 hours. Occlusive dressings can contribute to urinary retention and edema and should be removed. Stenosis of the now exposed urethral meatus may result from prolonged exposure to the ammonia in urine. Application of a Plastibell that is too small also can lead to meatal stenosis in 8 to 31% of cases.[18] Signs and symptoms include pain with urination, bloody discharge resulting from an inflamed meatus, high-velocity stream, and the need to sit while voiding. Postcircumcision phimosis may result if excess foreskin remains. If the constriction is severe and urinary outlet obstruction occurs, dilation of the stenosis can be performed with a hemostat. Surgical revision usually is necessary.[19]

Skin bridges are small fibrotic bands that attach the glans to the penile shaft and may form after circumcision. Inclusion cysts result from smegma retained in the wound or from epidermis involution along the circumcision site. Skin bridges and inclusion cysts are treated by surgical resection. These complications may be prevented by proper hygiene and application of an antimicrobial ointment to the circumcision site for 7 to 10 days after the procedure.

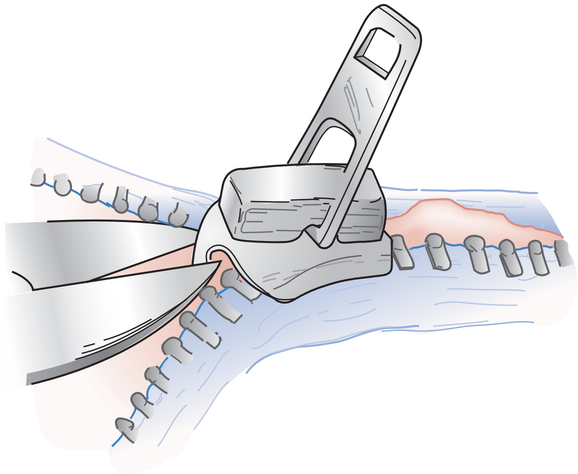

Figure 174-4. Release of zipper entrapment by cutting of the median bar. (From Snyder HM 3rd, et al: Genitourinary trauma. In Fleisher GR, Ludwig S [eds]: Textbook of Pediatric Emergency Medicine, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

Penile Entrapment and Tourniquet Injuries

Penile rings, string, wire, and human hair tourniquets can result in penile venous and arterial occlusion. The patient presents with swelling of the glans, wherein the offending agent may be difficult to visualize because of edema of the coronal sulcus. In addition to the vascular supply, the dorsal penile nerve supply can be occluded. The foreign body can be cut with small surgical scissors. Hair tourniquets have also been successfully removed with Nair. Once the foreign body is removed, urethral obstruction can be evaluated by means of retrograde urethrography, and Doppler ultrasonography can be performed to assess penile arterial blood flow. Once it is identified, the constriction is relieved, and the patient should not be discharged until spontaneous voiding is ensured. Urologic consultation may be necessary emergently if penile arterial flow is disrupted and the constricting object cannot be removed rapidly or signs of necrosis are present.

Zipper entrapment of the foreskin also can occur in children, typically those between 2 and 6 years of age. The zipper can be removed with bone or metal cutters or a mini-hacksaw to cut the median bar of the zipper[20,21] (Fig. 174-4). The zipper falls apart, and the foreskin is freed. Although local anesthesia is not necessary, the patient may be anxious and require sedation before its

www.ketabpezeshki.com 66485457-66963820

Figure 174-5. Epididymitis in a 5-year-old boy; note mild swelling and erythema on the left. (Courtesy Marianne Gausche-Hill, MD.)

removal. Success has been reported with soaking of the penis in mineral oil before zipper removal.[22] Additional methods to release the foreskin under the zipper mechanism include cutting of the zipper below the entrapment and pulling the two halves of the zipper apart; cutting of the zipper teeth above and below the entrapment and, with pliers, squeezing the median bar to allow more room to disengage the trapped prepuce; and insertion of a flat screwdriver between the faceplates of the zipper mechanism to pry open the faceplates and allow the prepuce to be released.[23-25] Parents should be instructed to encourage their children to wear underwear to decrease the risk of entrapment.

Scrotal Masses and Swelling

Epididymitis

Principles of Disease. Epididymitis is inflammation of the epididymis, which is located along the posterior aspect of the testicle. The most common cause is infectious, and the etiology varies by age. Adolescents should be evaluated for possible sexually transmitted diseases, such as *N. gonorrhoeae* and *Chlamydia trachomatis*. Patients may have a history of previous urinary tract infections, anatomic abnormalities, or previous genitourinary instrumentation. Urinary tract infections leading to epididymitis typically are caused by viruses or bacterial agents, such as *Escherichia coli, Klebsiella pneumoniae, Proteus,* or *Pseudomonas aeruginosa*.

Clinical Features. Patients present with a painful, edematous scrotum and tenderness at the epididymis (Fig. 174-5). A urethral discharge may be present, particularly when the condition is secondary to a sexually transmitted disease. Systemic signs and symptoms, such as nausea, vomiting, fever, and lower abdominal, scrotal, or testicular pain, also may be present. Infants and young children may present with fever without other symptoms. Accordingly, in the ED evaluation of all children with fever or other systemic symptoms or signs, a complete examination should include a genitourinary examination.

As the edema increases, obliteration of the sulcus between the testis and epididymis occurs, making differentiation from testicular torsion extremely difficult. Relief of pain with scrotal elevation (Prehn's sign) is unreliable.

Diagnostic Strategies. Urinalysis and urine culture should be part of the ED evaluation for all infants and children younger than 2 years. In children 2 years of age or older, urine culture may be performed only if the urinalysis results indicate urinary tract infection. Lack of pyuria does not rule out epididymitis because up to 50% of patients may have normal results on such studies. CBC may show leukocytosis, although this finding is nonspecific. Any urethral discharge should be cultured and sent for Gram's stain and tests for *N. gonorrhoeae* and *C. trachomatis*. Color Doppler ultrasonography is not necessarily performed in all children with suspected epididymitis. However, if there is doubt about the diagnosis, it is the preferred diagnostic study because it does not require placement of an intravenous line and is more readily available at all hours of the day. If color flow Doppler ultrasonography or radionuclide scintigraphy is performed, it will reveal a normal testis and preserved or increased vascular flow toward the side of the inflamed epididymis.[26,27]

Management and Disposition. Scrotal elevation, placement of ice packs on the swollen area as tolerated, and nonsteroidal anti-inflammatory or narcotic medications are useful to control pain and inflammation. If urethral discharge is present, the adolescent patient should be treated presumptively for both *N. gonorrhoeae* and *C. trachomatis*. The treatment for sexually acquired epididymitis in children 9 years of age or older consists of ceftriaxone 250 mg intramuscularly, followed by doxycycline 100 mg orally twice a day or tetracycline 500 mg orally four times a day. A single 1-g dose of azithromycin may also be used to increase compliance. Patients younger than 9 years should be treated with erythromycin 50 mg/kg orally per day, divided four times a day. The course of treatment typically ranges from 7 to 14 days, depending on the antibiotic regimen. In children, non–sexually acquired epididymitis without evidence of urinary tract infection may be managed expectantly with analgesics for pain.[28] Infants with or without positive findings on urinalysis and young children with positive urinalysis findings may be treated with trimethoprim twice a day or cephalexin three times a day if a bacterial urinary tract infection is suspected. Other antibiotic options include oral erythromycin, clarithromycin, and azithromycin for patients who do not respond to other therapies because *Mycoplasma genitalium* and *Ureaplasma urealyticum* may cause a more chronic form of epididymitis. Infants and children with epididymitis may be discharged for follow-up by their primary care physician, and urine cultures should be checked to determine definitively if urinary tract infection is present. Patients with systemic symptoms and toxicity should be admitted for intravenous antibiotic therapy with either ceftriaxone or cefotaxime. Children need close urologic follow-up to rule out any contributing anatomic abnormalities and to ensure that the antibiotic chosen treats the infecting organism.

Orchitis

Orchitis is a result of a bacterial or viral testicular infection leading to diffuse edema, pain, and discoloration of the scrotum. The most common pathogen is paramyxovirus, which can be the causative agent in up to 38% of postpubertal males with mumps-associated orchitis. Other etiologic agents include *E. coli, K. pneumoniae, P. aeruginosa, Staphylococcus* or *Streptococcus* species, Epstein-Barr virus, Coxsackievirus, arbovirus, enterovirus, *Brucella,* granulomatous disease, and filariae.

During the course of mumps, orchitis usually develops after the first week and is manifested with tenderness and edema of the testis with discoloration of the scrotum. Bilateral cases are relatively rare, occurring in 2 to 5% of affected patients. If epididymitis coexists, a urethral discharge also may be present. Bacterial orchitis can result in scrotal abscess formation. Because orchitis typically is unilateral, fertility usually is maintained.

Doppler ultrasound imaging may be necessary to distinguish orchitis from testicular torsion. For patients with a clearly viral origin such as mumps, treatment is aimed at pain control (scrotal elevation, nonsteroidal anti-inflammatory agents, and possibly narcotics). When the diagnosis is unclear or when concurrent epididymitis is present, empirical treatment includes oral antibiotics with predominantly gram-negative organism coverage. Hospital admission is warranted for patients who have a toxic appearance or exhibit evidence of a scrotal or testicular abscess or in whom

www.ketabpezeshki.com 66485457-66963820

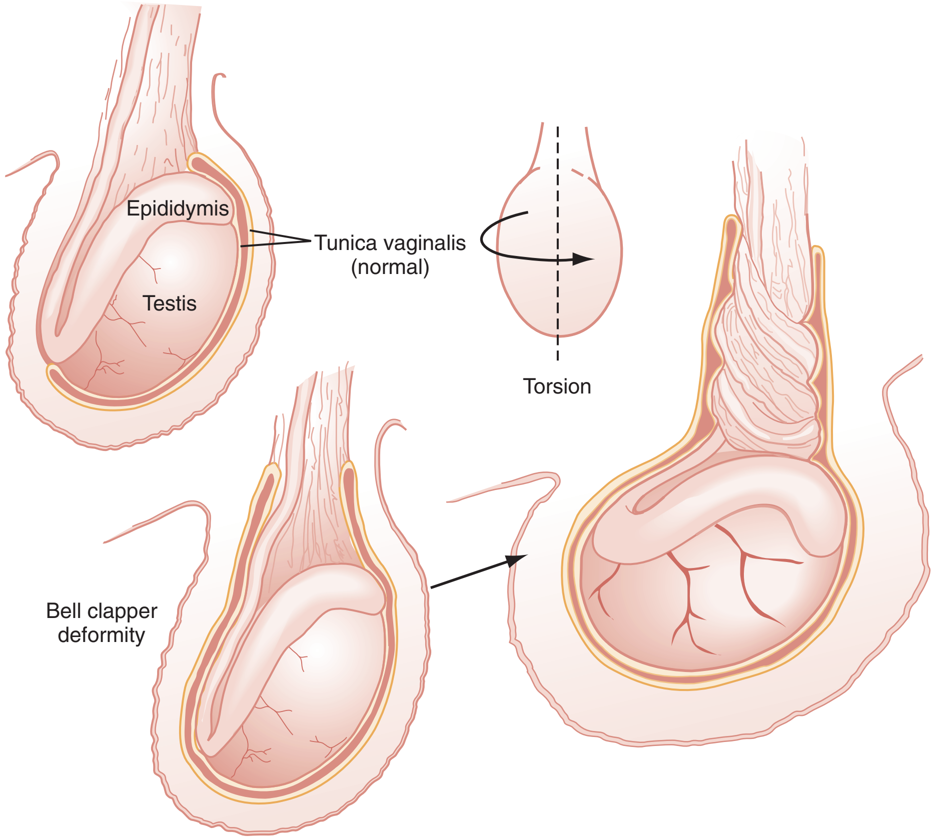

Figure 174-6. Anatomy of testicular torsion. (From Snyder HM 3rd, et al: Pain—scrotal. In Fleisher GR, Ludwig S [eds]: Textbook of Pediatric Emergency Medicine, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

outpatient management has failed. Urologic follow-up should be arranged.

Testicular Torsion

Principles of Disease. Torsion of the spermatic cord is a common cause of an acutely painful scrotum. Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, necrotic, gangrenous testes. Testicular salvage rates are time dependent; the success rate is 96% if detorsion is performed less than 4 hours from symptom onset, decreasing to less than 10% if there is more than a 24-hour delay to treatment.[29] The overall incidence of testicular torsion is 1 in 4000, with a peak incidence at age 13 years. Testicular torsion has been reported in all age groups, from the developing fetus to the elderly, but is most common in adolescence.

The testis enters the scrotum through the inguinal canal after descent from the abdomen. The peritoneum invaginates through the canal and partially covers the testis and epididymis, forming the tunica vaginalis. Typically, the tunica vaginalis attaches to the posterior wall of the hemiscrotum and superior pole of the testis to achieve testicular fixation. If the tunica completely covers the testis and attaches higher up on the spermatic cord (bell clapper deformity), proper testicular fixation does not occur, and there is a predisposition to torsion (Fig. 174-6). In intravaginal torsion, the testicle may rotate within the tunica vaginalis, thereby constricting the arterial blood flow. Extravaginal torsion is seen most commonly in neonates who are premature and also can occur antenatally.

Clinical Features. Patients present with acute scrotal pain and swelling, an elevated testicle, and, typically, absence of the cremasteric reflex.[30] This reflex can be demonstrated by lightly stroking the skin of the inner thigh downward from the hip toward the knee. This causes the cremaster muscle on the ipsilateral side to contract rapidly and results in elevation of the testicle. Although in one series the cremasteric reflex was absent in 100% of patients with torsion and in only 14% of patients with epididymitis, the presence of the cremasteric reflex does not preclude testicular torsion. Abnormal epididymal and testicular position also may be noted, with left-sided torsions slightly more common than right. Nausea, vomiting, and a low-grade fever also may be seen. In the patient with an undescended testicle who presents with abdominal pain, torsion should be a consideration.[31]

Diagnostic Strategies. Unless an alternative diagnosis is absolutely secure (e.g., epididymitis), the patient should be evaluated for testicular torsion. Alternatively, with a relatively confident clinical diagnosis of torsion, diagnostic testing should not delay appropriate management. Results of a urinalysis are rarely helpful as pyuria can be seen in cases of testicular torsion and epididymitis. The widely preferred diagnostic study for the prospect of torsion is color flow Doppler ultrasonography. This technique has a sensitivity of 79 to 86%, with a specificity of almost 100%, for detection of testicular torsion. Scintigraphy has a sensitivity ranging from 79 to 100% and a specificity of 89 to 100%.[27,32,33] Magnetic resonance imaging has been evaluated as another diagnostic modality, with a sensitivity in one study of 93% and specificity of 100%.[34] In cases of indeterminate ultrasound findings, the urology consultant should be notified for disposition decisions; in addition, scintigraphy may be performed as resources allow. When clinical suspicion is strong, surgical exploration should not be delayed for diagnostic studies, especially in patients in whom duration of symptoms is less than 12 hours.

Management. If the patient presents within 12 hours of symptom onset, immediate surgical exploration is indicated,

www.ketabpezeshki.com 66485457-66963820

predicated on clinical findings or confirmatory clinical studies.[35] Detorsion of the affected testicle is performed, followed by an elective orchiopexy of the contralateral side to avoid recurrence. Approximately 40% of patients have a bell clapper deformity of the contralateral testicle. Manual detorsion also may be performed by rotation of the testicle in an "open book" fashion as viewed from below, from medial to lateral, until detorsion is complete.[36] Because the procedure is painful, sedation and pain relief should be considered before this intervention. Manual detorsion should be attempted only if there is a delay in getting a urologist to come in for operative detorsion and the patient has had continuous pain for less than 24 hours or if, in the judgment of the emergency physician, the time zone of opportunity to salvage the testis has not passed.

Torsion of the Testicular Appendage

The appendix testis is a remnant of the müllerian duct. The appendix testis is involved in 92% of the cases of testicular appendage torsion, and the appendix epididymis is involved in the remaining cases. The average age at occurrence is 10 years. Patients typically present with moderate pain of sudden onset that is localized to the involved hemiscrotum. The pathognomonic "blue dot" sign, a small area with a bluish hue less than 3 mm across located in the upper lateral portion of the hemiscrotum, is present in less than 25% of cases and represents the cyanotic appendage below the scrotal wall. If any doubt exists about the diagnosis, a nuclear radioisotope scan or color Doppler ultrasound study should be performed. Color Doppler ultrasonography reveals normal or increased flow to the affected testicle. Conservative therapy with analgesics and scrotal support are usually all that is indicated; the involved appendage undergoes autoamputation within 1 week, accompanied by resolution of symptoms.

Varicocele

A varicocele is a collection of venous varicosities of the spermatic veins in the scrotum caused by incomplete drainage of the pampiniform plexus. Incidence rates of 14 to 16% in adolescent males have been reported,[37] but varicoceles are rare in children younger than 10 years.[38] Left-sided varicoceles account for 85 to 95% of cases; however, bilateral varicoceles may be present in up to 22% of patients.[39] Intra-abdominal disease should be suspected in cases of right-sided varicocele because these usually are caused by inferior vena cava thrombosis or compression of this vessel by tumors.[40] The acute presentation of a left-sided varicocele should raise suspicion for renal cell carcinoma with obstruction of the left renal vein.

The dilated venous collection may be tender on physical examination. It can be palpated superior and posterior to the testis and usually is more pronounced with the patient in the upright position. Therefore, the patient should be examined in both the standing and supine positions. Patients in whom scrotal swelling persists in the supine position should be evaluated with a computed tomography (CT) scan of the abdomen, with oral and intravenous contrast administration for conditions obstructing the renal vein. Varicoceles have been described as a "bag of worms" both in appearance and on palpation. Surgical correction may be required if the patient becomes symptomatic or has bilateral varicoceles.[41]

Idiopathic Scrotal Edema

Idiopathic scrotal edema is painless erythema and induration of the scrotum; 77% of cases occur before the age of 10 years. Two thirds of cases are unilateral, and no specific causes have been identified. The condition is characterized by the development of painless erythema and induration of the scrotum, which may be pruritic. There is minimal tenderness on physical examination, but the edema and erythema may extend to the phallus, groin, and abdomen. Examination of the testes and epididymis reveals no palpable masses. Systemic signs and symptoms are rare. Patients can be discharged home with outpatient follow-up after an acute pathologic process has been ruled out. Most cases resolve spontaneously within a few days and do not require any specific treatment. Recurrence rates of up to 21% have been described.

Hydrocele

A hydrocele is a collection of fluid that accumulates in the tunica vaginalis. Communicating hydroceles result when the upper processus vaginalis fails to be obliterated, leaving an open tract between the peritoneum and the scrotum. The tract is closed in noncommunicating hydroceles. Most hydroceles are right sided. They may be present at birth, but they usually are painless and worsen with crying or exertion. Hydroceles often resolve spontaneously by the age of 18 months. Examination with transillumination reveals enlargement of the scrotum. Color flow Doppler ultrasonography or radionuclide scintigraphy may be necessary to determine the cause of the hydrocele and to exclude an acute pathologic process in patients with acute symptoms of pain; otherwise, asymptomatic patients can be discharged home with urologic follow-up. Patients with a hydrocele that has persisted for more than 1 year or who are older than 18 months should undergo ultrasonography to ensure that the hydrocele is not a reactive hydrocele caused by testicular tumor or inflammation.

Inguinal Hernia

Principles of Disease. Inguinal (direct and indirect) hernias are more common in males, with bimodal peaks before 1 year of age and then again after the age of 40 years. An indirect inguinal hernia occurs when the processus vaginalis is not obliterated in infancy and abdominal contents invaginate through this patent sac. Entrapment of mesentery, bowel, intraperitoneal organs, and the hernial sac can occur and is more common with small hernias. If the contents of the hernia can be returned to their anatomic position, the hernia is reducible; if the contents remain entrapped, it is incarcerated or irreducible. Hernias that remain incarcerated can undergo strangulation, with resultant necrosis of bowel or mesentery.

Clinical Features. Patients with incarcerated hernias may present with pain, edema extending to the scrotum, nausea, vomiting, and low-grade fever. Physical examination may reveal bowel sounds in the scrotal sac. If the inguinal mass can be palpated separately from the testes, it is possible to diagnose an inguinal hernia on clinical grounds alone. Rarely, the incarcerated and strangulated hernia can be manifested as a tense blue mass in the scrotum.

Management and Disposition. The patient should be placed in the Trendelenburg position with an ice pack applied to the groin to reduce swelling; sedation may be necessary before reduction. Slow, gentle pressure should be applied to reduce the hernia. If the pressure technique is not successful in reducing the hernia, the opposite technique can be tried: the hernia mass can be "pulled" to straighten out the entrapped contents, thereby allowing them to slip back into the abdomen.

If the hernia cannot be reduced or strangulation is suspected (as indicated by fever, overlying cellulitis, or signs of peritonitis), the patient should receive fluid resuscitation, broad-spectrum parenteral antibiotics, and an emergent surgical consultation.[42]

Patients who are found to have a hernia on routine examination or who have had the hernia reduced and are without symptoms suggestive of incarceration or strangulation should be referred for surgical repair.

www.ketabpezeshki.com 66485457-66963820

Carcinoma

Principles of Disease. Testicular and scrotal cancer represents approximately 1% of solid tumors in children. An increased incidence of testicular cancer, in both the undescended testicle and the contralateral descended testicle, has been noted in patients with cryptorchidism. Tumor types include teratomas, embryonal carcinomas, yolk sac tumors, choriocarcinomas, Leydig cell tumors, and Sertoli cell tumors. Lymphoma and leukemia can metastasize to the testicle as well.

Patients typically present with a painless unilateral mass palpated separately from the testis or may describe a feeling of fullness, tugging, or increased weight of the scrotum and testicular enlargement. A reactive hydrocele may be present in 7 to 25% of patients and can lead to a delay in diagnosis. Physical examination reveals a firm mass, smooth or nodular, that cannot be transilluminated. A complete physical examination looking for lymphadenopathy, petechiae, abdominal mass, hepatosplenomegaly, or gynecomastia should be performed.

Diagnostic Strategies. Diagnostic evaluation includes a CBC, urinalysis, urine human chorionic gonadotropin (produced by germ cell tumors) assay, and ultrasonography of the testis.

Management and Disposition. ED management includes prompt referral for urologic and oncologic consultation. Admission to the hospital to facilitate the evaluation may be necessary.

Urinary Tract Infections

Perspective

Sequelae of untreated urinary tract infections may include sepsis and renal scarring, and accurate and early diagnosis is important. At the same time, avoidance of unnecessary evaluation and treatment of children at lower risk for these infections is cost-effective and minimizes the chance for iatrogenic harm. Diagnosis of urinary tract infections in infants and young children can be challenging because the clinical signs often are nonspecific, and it can be difficult to obtain useful urine specimens.

Principles of Disease

The risk for development of urinary tract infections before the age of 12 years is approximately 3% for girls and 1% for boys. Neonatal boys are more susceptible than girls to urinary tract infections, but beyond that period, infections in females prevail. Girls younger than 2 years and uncircumcised boys younger than 6 to 12 months also are especially at risk.[43]

Approximately 5% of children younger than 2 years with a temperature above 39° C and presenting without a source for the fever have an occult urinary tract infection.[44] Urinary tract infections are also significant in the very young infant, with up to 9% prevalence in one study of febrile infants younger than 60 days.[45,46] Fever duration also appears to correlate with the prevalence of urinary tract infections. Two days of fever was more likely than one day to be associated with a urinary tract infection.[44] Other risk factors for female infants include white race, age younger than 12 months, temperature above 39° C, and no other identifiable source for the fever.[44] Risk factors for male infants include nonblack race, similar temperature, and no other identifiable source for the fever.[44] Moreover, up to 4% with a significant fever and an associated upper respiratory tract infection or acute otitis media also may have a urinary tract infection.[47] By comparison, the background prevalence of asymptomatic bacteriuria is estimated to be 1 to 2% in all children.[48]

On the basis of renal nuclear scans, it is estimated that 75% of children younger than 5 years with a febrile urinary tract infection have pyelonephritis.[45] Vesicoureteral reflux from the bladder into the ureter is a common cause of the pyelonephritis and renal scarring. Urinary tract infection in infants younger than 3 months is associated with bacteremia in up to 50% of cases; in children older than 3 months, the risk drops to 5%. Renal scarring can occur in 27 to 64% of children after pyelonephritis and may lead to renal failure and a risk for hypertension later in life.[45]

E. coli is the predominant cause of urinary tract infections in children; *Klebsiella* species are more likely to be the etiologic agents in newborn children. *Enterobacter, Proteus, Morganella, Serratia,* and *Salmonella* species also are important pathogens.[49] Organisms such as *Lactobacillus,* coagulase-negative staphylococcus, and *Corynebacterium* are not considered clinically relevant pathogens in otherwise healthy children.[44] In neonates and young infants, bacteremia is considered the route of infection to the urinary tract. In older children, infection in the lower tract often is the source of upper tract infection. A common cause of urinary tract infections in toilet-trained girls is believed to be improper wiping after urination. Young girls should be taught to wipe from anterior to posterior (front to back) after urination.

Clinical Features

Infants and Children Younger than 2 Years. Signs and symptoms usually are nonspecific and include decreased oral intake, lethargy, jaundice, fever, vomiting, abdominal pain, and irritability. Young children may not be able to verbalize when urination is painful. It is assumed that a urinary tract infection in this age group represents upper tract disease and would therefore arise with more systemic symptoms and signs.

Children Older than 2 Years. Urinary tract infection in children older than 2 years can be either an isolated cystitis or upper tract disease with symptoms and signs of a more systemic nature. Cystitis usually is associated with local symptoms (i.e., suprapubic tenderness and dysuria). Clinical manifestations of pyelonephritis may include fever, costovertebral angle tenderness to palpation, abdominal pain, vomiting, and ill appearance. New-onset bedwetting also may be a sign of a urinary tract infection.

Diagnostic Strategies

Various techniques can be used for collection of urine samples from children. Because of the difficulty in cleaning the perineal area, the bag collection method is associated with an increased risk of contamination by periurethral flora; false-positive results range from 12 to 83%.[45] Because urethral catheterization is almost always successful, suprapubic aspiration to obtain a urine sample is rarely needed.[48,49] A suprapubic bladder aspiration may be used for young infants because the expanded bladder is located more intra-abdominally. Bladder aspiration is considered more invasive and is more painful than the urethral catheterization method.[44] Chances of a full bladder and successful aspiration improve if 45 to 60 minutes have elapsed since the last diaper change. Ultrasonographic guidance has been advocated to enhance the probability of obtaining urine by the suprapubic and catheterization methods. Nursing staff can be trained to use this enhanced method of urinary collection.[50,51]

Urethral catheterization is relatively simple and poses little risk, although it may be more difficult in uncircumcised boys or in young infants. There is a slight risk of both trauma to the urethra and introduction of bacteria into the urinary tract with this technique. A 5-F feeding tube can be used in young infants. Young male infants sometimes spontaneously urinate when the urethral meatus is cleansed; a midstream clean-catch urine specimen may then be obtained.

For a clean-catch urine sample from a toilet-trained child, the parent can clean the child's urogenital area with soap and water before urination. Children can be instructed to sit backward on

www.ketabpezeshki.com 66485457-66963820

the toilet to urinate, allowing better access to obtain the urine specimen. A urine sample with more than 10 white blood cells (WBCs) per high-power field and a large number of epithelial cells should be considered contaminated, and either an improved clean-catch method or catheterization should be tried. Females with a vaginal discharge, regardless of age, should be catheterized.

In children younger than 2 years, a urinalysis alone is not considered adequate to rule out urinary tract infections. As many as 10 to 50% of patients with urinary tract infection can have false-negative results on urinalysis.[52,53] Nitrite and leukocyte esterase urinalysis markers have the highest combined sensitivity and specificity for detection of infection. If both markers are positive, the false-positive rate is less than 4%. The urine dipstick alone appears to work less well in young infants.[45,55] Gram's stain of the urine has a sensitivity of 93%.[45,55] New guidelines have redefined urinary tract infections in children. To establish the diagnosis of urinary tract infection in children, the clinician should require both of the following: (1) urinalysis results suggesting infection (pyuria, bacteriuria, or both) and (2) the presence of at least 50,000 colony-forming units (CFU) per milliliter of a uropathogen cultured from a urine specimen.[44] Old guidelines of 100,000 CFU/mL were based on studies of adult women and are considered no longer applicable to children.

Renal function tests are rarely abnormal but should be performed in children with hypertension, proteinuria, or signs of dehydration. In general, blood cultures are not indicated in a majority of well-appearing children with urinary tract infection. The true-positive rate for blood culture in the presence of a urinary tract infection in older infants and young children is low, and the organism identified is invariably the same as the organism in the urine culture.[56]

Differential Considerations

Underlying renal disease or urinary tract abnormality should be considered in a child presenting with hypertension, hematuria, or difficulty with urination; it should be suspected in children with elevated BUN or creatinine concentration, electrolyte abnormalities, or acidosis on laboratory examination. CT of the abdomen may be necessary to delineate the extent of urinary tract abnormalities.

Several other causes of dysuria in children are recognized (Box 174-1). Irritants such as bubble bath and soaps may cause local irritation and dysuria. A retained foreign body in the vagina or penis (such as toilet paper) can cause irritation or bacterial growth with associated dysuria and vaginal discharge. Pinworms in the genitourinary area can cause itching and scratching. Balanitis in uncircumcised boys also can cause dysuria and pyuria.

Accidental injuries to the genital area can cause abrasions or lacerations and subsequent dysuria. Sexual or physical abuse should be considered in any young child with a history of multiple urinary tract infections.

Box 174-1 Etiology of Dysuria in Children

Infection
- Urinary tract infection, including cystitis and pyelonephritis
- Vaginitis resulting from *Gardnerella, Trichomonas, Candida,* or sexually transmitted organisms
- Pinworms
- Balanitis

Irritation
- Bubble bath, new soaps, or douches
- Vaginal foreign body, such as retained toilet paper

Trauma
- Sexual or physical abuse
- Straddle injury (unintentional)
- Self-stimulation or masturbation

Other
- Labial adhesions
- Renal stones or hypercalciuria

Management

Children who are considered "ill appearing" or "toxic" or who are unable to take oral medications should be treated with parenteral antibiotics until clinical improvement, generally 24 to 48 hours, and they are able to retain oral medications and fluids. If compliance is in question, parenteral antibiotics should also be considered.

Infants Younger than 2 Months. Young infants with urinary tract infections are at risk for associated sepsis. The age at which a urinary tract infection warrants hospital admission has decreased dramatically. Infants younger than 2 months are still considered to be at high risk for the development of sepsis and should therefore be admitted to the hospital for intravenous antibiotic therapy (e.g., with gentamicin and ampicillin). One study, however, showed low adverse events in young infants (29-60 days of age) diagnosed with a urinary tract infection who appeared well in the ED and did not have a high-risk past medical history.[57-59]

Children 2 Months to 2 Years. Although inpatient treatment of children with suspected pyelonephritis has traditionally been recommended, studies now show that well-appearing children without signs of toxicity may be managed as outpatients.[60] A meta-analysis of data from both adult and pediatric studies found no significant evidence suggesting that oral antibiotic therapy is less effective than parenteral or initial parenteral therapy for treatment of severe urinary tract infection.[61] Choices of oral antibiotics include a cephalosporin, amoxicillin with clavulanic acid, and trimethoprim-sulfamethoxazole.[44] Antibiotics that are excreted in the urine but do not reach sufficient levels in the bloodstream, such as nitrofurantoin, should not be used.[44] Community antimicrobial resistance patterns are important to consider in deciding on an appropriate antimicrobial. Rates of *E. coli* resistance to trimethoprim-sulfamethoxazole can be as high as 20 to 30% in some communities.[62] The first dose of a parenteral antibiotic and a double dose of an oral antibiotic appear to be equivalent. Because urinary tract infections in this age group are considered to be upper tract disease processes, a longer course of antimicrobials is indicated (e.g., 7 to 14 days). Although a review of studies found no difference in the frequency of positive urine cultures between short-course therapy (2 to 4 days) and longer course therapy (7 to 14 days), most of these studies mixed children younger than 2 years with older children, including adolescents. Thus the recommendation for short-course therapy in children younger than 2 years is not supported at this time.[44,63] Follow-up in 2 to 3 days is essential to evaluate the culture and sensitivity results and to assess clinical status. Older recommendations required both ultrasonography and voiding cystourethrography to be performed on all infants with first-time urinary tract infections. Newer recommendations focus only on a renal and bladder ultrasound examination looking for evidence of renal scarring or anatomic abnormalities that require further evaluation. For children who clinically improve quickly, this ultrasound examination can be done at a later time on an outpatient basis.[44]

Children Older than 2 Years. In older children with simple cystitis, a short 3-day course of antibiotics, such as trimethoprim-sulfamethoxazole or amoxicillin-clavulanate, is adequate. Shorter courses result in higher failure rates and are not indicated. In older children with pyelonephritis, a longer course of antibiotics (generally 7-14 days) is recommended.[44] In the adult population, a study

www.ketabpezeshki.com 66485457-66963820

showed that a 7-day course of a fluoroquinolone is as effective as a 14-day course of trimethoprim-sulfamethoxazole.[64] In children, fluoroquinolones are still contraindicated because of the concern for their effect on skeletal development.[65]

Disposition

Children with signs of toxicity, urinary obstruction, or inability to take oral medications should be hospitalized for intravenous antibiotic therapy.[66] On discharge, parents should be instructed to return if the child is unable to take the oral medication or if the symptoms worsen. The child may remain febrile for 48 hours despite adequate antimicrobial therapy. The child's clinical status should be checked in 48 to 72 hours, either in person or by telephone. At follow-up, the urine culture results should be checked to ensure appropriate antimicrobial therapy.[67]

Hematuria

Perspective

Hematuria is common in the pediatric population. Hematuria, defined as the presence of red blood cells (RBCs) on examination of two successive urine samples, has a prevalence rate of 1 to 2% in children 6 to 15 years of age.[68] Microscopic hematuria is defined as the presence of more than 5 RBCs/mm^3 and is detected by chemical reagent strips and microscopic urinalysis. Persistent hematuria is defined as positive results on three urinalyses during a 2- to 3-week period.[68] Macroscopic or gross hematuria is presence of blood in the urine visible to the naked eye and may be associated with clots.

Box 174-2 Etiology of Hematuria in Children

Extrarenal
Trauma
Meatal stenosis or posterior urethral valves
Exercise
Menstruation or rectal bleeding
Foreign bodies
Cystitis, urethritis, or epididymitis

Intrarenal
Pyelonephritis
Renal or bladder stones or tumors
Poststreptococcal or idiopathic glomerulonephritis
Acute interstitial nephritis
Acute tubular necrosis
Basement membrane glomerular disease
Renal vein or artery thrombosis
Recurrent familial hematuria
Polycystic kidney disease

Systemic
Henoch-Schönlein purpura
Systemic lupus erythematosus
Hemolytic-uremic syndrome
Infectious mononucleosis
Sickle cell disease or other hemoglobinopathies
Bacterial endocarditis or artificial cardiac valves
Bleeding disorders, warfarin, or aspirin
Medications such as amitriptyline or chlorpromazine, radiocontrast dyes
Munchausen syndrome or factitious

Principles of Disease

Hematuria results from the entry of RBCs into the urinary tract. Inflammation, infection, trauma, or anatomic abnormalities can occur anywhere from the glomerulus to the urethra. The endothelium and basement membrane of the glomerulus usually are impervious to large proteins such as RBCs and hemoglobin, but myoglobin may pass freely. Damage to the glomerulus, however, may allow RBCs and hemoglobin to pass into the collecting system.

Urine with lysed RBCs tests positive for hemoglobin and negative for RBCs and may be pink. Urine containing myoglobin from muscle breakdown tests positive for hemoglobin and negative for RBCs. Evaluation of creatine kinase and fractionated bilirubin levels and hematocrit often can help differentiate hemoglobinuria from myoglobinuria. Not all red urine contains blood. Certain drugs or foods, such as phenothiazines, ibuprofen, beets, and blueberries, can cause reddish urine. In neonates, urate crystals can cause red-tinged urine in the diaper. *Serratia marcescens,* a fecal pathogen, can cause a red pigmentation when left in the diaper. Bleeding from the vagina or rectum can sometimes be mistaken for blood in the urine.

Clinical Features

The history and physical examination should focus on signs of infection, trauma, or bleeding disorders. Signs of renal disease (e.g., hypertension), edema, rales, and cardiac murmurs are important findings. An examination of the genitalia may reveal inflammation or bleeding.

Differential Considerations

The etiology of hematuria comprises a diverse group of disorders and conditions (Box 174-2). Presence of RBCs in the urine as a result of trauma is discussed elsewhere.

Extrarenal causes of hematuria include urethral valves and meatal stenosis. Extensive exercise can also cause hematuria or myoglobinuria as a result of both direct renal trauma and ischemic injury.

Intrarenal disorders include pyelonephritis, renal or bladder tumors, poststreptococcal acute glomerulonephritis, and basement membrane disease of the glomerulus.

Systemic illnesses that cause hematuria, such as Henoch-Schönlein purpura and hemolytic-uremic syndrome (HUS), are discussed later in this chapter. Other systemic causes of hematuria include bleeding disorders, aspirin, and anticoagulants.

Diagnostic Strategies

A urinalysis that shows more than 5 RBCs per high-power field indicates hematuria. The presence of WBCs or leukocyte esterase should be noted. RBC casts in the urine or significant proteinuria demonstrates a glomerular origin for the hematuria. If glomerular disease is suspected, a throat culture, antibody test for streptococcus, complement studies, erythrocyte sedimentation rate determination, antinuclear antibody assay, or hepatitis B serology tests should be considered. If the patient has signs of hypertension, edema, or proteinuria, laboratory tests for electrolytes, total protein, and albumin should be ordered.[69]

If the cause of the hematuria is still unclear, follow-up with the patient's pediatrician for a 24-hour urine collection for creatinine and protein is important. Because hypercalciuria is common in children, urine and plasma calcium levels should also be measured as they will give a better indication of the cause of the hypercalciuria.

Because younger pediatric patients have predominantly renal stones rather than ureteral stones, ultrasonography can be used as the first-line imaging modality for the diagnosis of renal stones in institutions with dedicated pediatric ultrasonographers. Should the ultrasound study be normal in a patient when renal stones are

www.ketabpezeshki.com 66485457-66963820

still a concern, a non–contrast-enhanced helical CT scan can then be ordered.

Management

Management of the child with hematuria depends on the underlying cause. The management of the child with renal stones and renal tumors is discussed later in the chapter.

Disposition

The disposition of a child with hematuria depends on the underlying cause. Simple cystitis or pyelonephritis can be treated in the ED with follow-up by the child's primary care physician. A child diagnosed with a renal tumor or stone should be referred to a nephrologist or urologist. Children with acute renal failure, especially those with signs of fluid overload or hyperkalemia, need to be hospitalized for appropriate management. For children with no known cause of the hematuria but who appear well in the ED, follow-up with their own pediatrician in the next 1 to 2 weeks is important. Persistent hematuria with no known cause should be followed up by a nephrologist for further evaluation.

Renal Stones

Perspective

Renal stones result from a complex process of crystallization involving growth inhibitors and promoters and changes in urine pH and flow. Congenital abnormalities, trauma, or infection also can be an inciting cause. An increased risk for hypercalciuria and the formation of renal stones often is inherited.

Principles of Disease

Renal stones are uncommon in children, with approximately 1 case diagnosed for every 1000 pediatric hospital admissions.[70] Calcium-containing stones are responsible for approximately 60% of all cases, followed by struvite, uric acid, and cystine stones.[70] Struvite stones are composed of ammonium, magnesium, and phosphate and are potentiated by urea-splitting organisms such as *Proteus, Pseudomonas,* and *Klebsiella*. Renal stones are three to four times more common in white children than in nonwhite children. Family history also seems to play a role in the formation of kidney stones.[71] In younger pediatric patients, renal stones predominate over ureteral stones.[72]

Clinical Features

The signs and symptoms of renal stones in older children typically include colicky flank pain, vomiting, and hematuria. Younger children with renal stones also can present with less specific complaints, such as nontender abdominal pain, vomiting, or malaise. In a study from the United Kingdom, 17% of pediatric patients with renal stones were found to present with hematuria only, without flank or abdominal pain.[71] In the initial evaluation of children with possible renal stones, the history should ascertain potentially relevant factors, including previous urinary tract infections (especially those caused by organisms such as *Proteus* species), family history of renal stones, and diet (including excessive vitamin use) and fluid intake. Toxins introduced into the human food supply have also been associated with the development of renal stones as was seen in China with melamine-contaminated powdered infant formula.[73]

Obstruction of the collecting system can sometimes lead to infection, papillary necrosis, or decrease in renal function. Fever in the presence of a renal stone should be taken as an indicator of upper tract infection.

Diagnostic Strategies

In children thought to have renal stones, the urine should be checked for hematuria and evidence of infection, such as positive leukocyte esterase or nitrites, leukocytes, and bacteria. The urine also should be strained and any crystals sent for analysis. Other laboratory tests to consider are CBC, electrolyte panel, and determination of BUN, creatinine, uric acid, total protein, and albumin levels. Ninety percent of renal calculi are visible on a plain abdominal radiograph, although stool can sometimes obscure the view. Other types of calcifications appearing on plain abdominal radiographs are gallstones, phleboliths, vessel or lymph node calcifications, and calcified malignant neoplasms. Plain films of the abdomen have no additional value over CT scan of the abdomen and should not be obtained in lieu of the CT scan or other imaging.

Non–contrast-enhanced helical CT is the current study of choice for the identification of renal and ureteral stones. It has exceptional sensitivity and specificity for detection of calculi as small as 1 mm and can identify associated processes, such as obstruction, hydroureter, hydrocalyx, and renal abscess. In addition, it is superior to intravenous pyelography in determining alternative diagnoses, such as abdominal tumor. In children, however, the risk of ionizing radiation with CT scanning pushes clinicians to look for alternative forms of imaging. Because renal stones predominate over ureteral stones in younger pediatric patients, ultrasonography is a viable alternative for imaging in this population. In one study, sensitivity of ultrasonography was 90% for renal stones and 38% for ureteral stones.[72] Ultrasonography for renal stones in pediatric patients will be of highest utility in institutions with a large pediatric patient volume and dedicated pediatric ultrasonographers. The use of CT scanning in smaller institutions or after a normal ultrasound study in a patient in whom renal stones are still a concern is a reasonable approach.

Differential Considerations

The differential diagnosis for colicky flank or abdominal pain in the pediatric patient generates a long list of possibilities. Gastroenteritis and constipation are more common than kidney stones as causes of colicky abdominal pain in young children. Intussusception most commonly occurs in children younger than 2 years and can be manifested with intermittent abdominal pain. In adolescents, biliary colic and intermittent gonadal torsion also must be considered.

Management

Initial pain management should include a narcotic analgesic in conjunction with a longer-acting nonsteroidal anti-inflammatory drug (NSAID). The analgesic effect of NSAIDs is directly related to the inhibition of prostaglandin-mediated contraction of the ureter and is characteristic of all NSAIDS (e.g., ibuprofen, naproxen, ketorolac). Patients with signs of volume depletion or with a history of fever, vomiting, or poor fluid intake should be adequately hydrated to improve urine flow and to prevent urinary stasis, which may contribute to stone formation. Excessive fluid administration to increase urine flow has not been proved effective, however, to enhance movement of the stone down the urinary tract. Although tamsulosin, an alpha-blocker, has been shown to be effective in adults to increase the passage of kidney stones, there are no significant studies in children to support the practice. One review of hospitalizations of children for renal stones found, however, that the use of tamsulosin had increased in the hospitals

www.ketabpezeshki.com 66485457-66963820

surveyed from less than 1% to more than 8% in pediatric patients during the years surveyed.[74]

After culture specimens have been obtained, children with infected urinary tracts with stones should be treated with antibiotics; hospitalization generally will be required. Children with larger renal stones may undergo shockwave lithotripsy as a therapeutic modality. In some centers, ureteroscopy also may be a management option for larger stones.[75]

Children with normal renal function and adequate pain control, without signs of toxicity or renal infection, can be safely discharged home with good follow-up. Several studies have shown that stones 5 mm or smaller appear to pass safely in pediatric patients.[76] Follow-up with a nephrologist or urologist may include parathyroid hormone assay, analysis of fasting urine samples for calcium-to-creatinine ratio, or 24-hour urine collection for determination of calcium, magnesium, phosphorus, uric acid, oxalate, cystine, protein, and creatinine levels.[70,77]

Renal Tumors

Perspective

Abdominal masses in children are not uncommon, and in infants most are benign renal tumors or cysts.[78]

Principles of Disease

Renal tumors in children can range from the benign cystic nephroma to the more aggressive malignant rhabdoid tumor. The prognosis will depend on the type and staging of the renal tumor.

Clinical Features

The most frequent presentation for a child with a renal tumor is that of an abdominal mass found by the parent while bathing or dressing the child. Hematuria or pain is a less common presenting manifestation than in the adult population.

Diagnostic Strategies

Because a significant number of abdominal masses are the result of renal cysts, renal ultrasonography is the imaging study of choice. Ultrasonography can define the mass in question and is not associated with exposure to ionizing radiation. Laboratory tests should include CBC, platelet count, BUN and serum creatinine concentrations, urinalysis, and urine catecholamine levels. Urinary catecholamines are increased in 95% of patients with neuroblastoma but are normal in those with Wilms' tumor. Any solid masses found on ultrasonography will be better defined by CT of the abdomen. If the mass appears malignant, a CT scan of the chest is indicated to look for pulmonary metastases.[79]

Differential Considerations

Considerations in the differential diagnosis for a renal mass include cystic lesions, such as those of polycystic kidney disease, and severe hydronephrosis resulting from obstruction or severe reflux. Solid masses include Wilms' tumor, renal cell carcinoma, mesoblastic nephromas, and cystic nephromas.

Management and Disposition

Management depends on the function of the urinary tract. Because the renal mass typically involves only one kidney, renal function usually is maintained.

A preliminary diagnosis of the cause of the mass should be obtained before discharge of the child from the ED. Well-appearing children with normal renal function for whom close follow-up can be ensured may be managed on an outpatient basis. Because of the potential seriousness of a renal tumor, hospital admission should be considered for all children. Consultations with a nephrologist, urologist, and hematologist-oncologist can be coordinated during the admission process.

Proteinuria

Perspective

The normal glomerulus is relatively impervious to albumin, a high-molecular-weight protein. Low-molecular-weight proteins, however, pass through the glomeruli and are reabsorbed in the proximal tubule. Proteinuria can result from either increased passage through the glomeruli or decreased reabsorption by the tubules. In most cases, proteinuria is benign and asymptomatic. If the amount of protein lost is significant, such as in nephrotic syndrome, the resultant hypoalbuminemia (albumin less than 2 g/dL and protein less than 4 g/dL) may cause ascites and generalized edema.

Principles of Disease

Proteinuria is a common finding in children. Trace to mild proteinuria (1+ to 2+) can be seen in up to 85% of children and adolescents screened, especially during the summer months.[80,81]

Clinical Features

Clinical features seen in a proteinuric child depend on the cause of the proteinuria. Recent pharyngitis, presence of hematuria, changes in weight or urine output, or family history of proteinuria should be investigated. Abnormal findings may include hypertension, edema, ascites, or palpable kidneys in infants. A butterfly rash of systemic lupus or the purpuric rash of Henoch-Schönlein purpura may be evident.

Differential Diagnosis

Causes of proteinuria can be divided into glomerular and tubular. Glomerular causes include nephrotic syndrome, glomerulonephritis, and post-transplantation rejection. Transient causes of altered glomerular function include exercise, fever, and seizures. Tubular causes of proteinuria include heavy metal poisoning, urinary tract infections, and diabetes; an asymptomatic tubular proteinuria also has been described.[80,81] False-positive results on urinary dipstick testing for proteinuria can be obtained when the urine is alkaline or when it contains mucus, blood, vaginal secretions, semen, or a significant number of inflammatory cells.

Orthostatic proteinuria is a benign condition characterized by the presence of protein in the urine collected with the patient in an upright position but not in samples collected from a supine child. Proteinuria that is persistent or associated with hematuria or other signs of renal disease usually is a sign of a more serious condition.

Diagnostic Strategies

Mild proteinuria (2+ or less; equivalent to 100 mg/dL or less) requires no further investigation unless there are signs of infection. Moderate proteinuria (3+ or more; equivalent to 300 mg/dL or more) necessitates additional evaluation with laboratory tests for serum total protein and albumin, serum electrolyte, BUN, and serum creatinine levels and urine culture. The child should be referred to a nephrologist, who can initiate a 24-hour urine collection for protein. The urine protein-to-creatinine ratio (urine

www.ketabpezeshki.com 66485457-66963820

Pr/Cr, expressed in mg/dL) in a random urine sample, however, correlates strongly with the protein levels found in a 24-hour urine collection.[80] Urine Pr/Cr of less than 0.2 mg/dL is considered normal for children older than 2 years and for adults. Children 6 months to 2 years of age normally have a ratio of less than 0.5 mg/dL. A urine Pr/Cr of more than 3.0 mg/dL is consistent with nephrotic syndrome.

Antistreptolysin O (ASO) titer can be measured to identify a previous streptococcal infection as the cause of the proteinuria. In young children, renal ultrasonography detects polycystic disease or anatomic abnormalities. Referral to the child's primary care physician or a pediatric nephrologist for follow-up and renal biopsy is indicated. Renal biopsy may be indicated in patients with increased creatinine levels, low complement levels, or hematuria.[82]

Management

The approach to management for a child found to have proteinuria depends on the underlying cause. Management of children with proteinuria involves assessment for signs of urinary infection, pharyngeal infection, and renal function. Other evaluation for poststreptococcal glomerulonephritis and nephrotic syndrome can take place on an outpatient basis unless the patient shows signs of systemic disease, hypertension, or renal failure.

Disposition

A child with significant edema and ascites from the loss of albumin needs to be hospitalized. Children with significant hypertension resulting from glomerulonephritis or with marked impairment of renal function also need to be hospitalized. Well-appearing children for whom good follow-up can be ensured can be discharged home.

Poststreptococcal Glomerulonephritis

Perspective

Poststreptococcal glomerulonephritis (PSGN) is one of the sequelae of streptococcal pharyngitis and, less commonly, infections of the skin. Treatment of streptococcal pharyngitis with antibiotics has not been shown definitively to decrease the incidence of PSGN, as opposed to acute rheumatic fever, another sequela of streptococcal pharyngitis. PSGN remains more of a cause of morbidity and mortality in developing countries and among impoverished populations.[83]

Principles of Disease

PSGN is not well understood but probably results from deposition of circulating immune complexes in the kidney.[84] This results in decreased glomerular filtration, allowing proteins to flow freely into the urine.

Clinical Features

PSGN most commonly occurs in children 3 to 7 years of age, usually with a history of pharyngitis with fever 2 weeks before the onset of glomerulonephritis. Symptoms can be localized to the urinary tract, manifested as hematuria or flank pain, or may be less specific, such as lethargy or generalized edema. Some children may present with more significant clinical signs, such as pulmonary edema, cardiac arrhythmias, or significant hypertension. Renal failure is found in 2% of these patients.[85,86] In one study, delay in diagnosis of PSGN was associated with a negative infection history and absence of gross hematuria.[87]

Diagnostic Strategies

Urinalysis shows significant blood and protein, with RBC casts in 60% of cases. Pyuria with granular or hyaline casts also may be found.

The ASO titer and immunoglobulin G levels are elevated in PSGN. Total complement levels, especially C3, are decreased in most patients during the first 2 weeks of the illness. The complement levels should return to normal within 3 to 4 weeks. The BUN concentration is elevated; hyponatremia and hyperkalemia also may be present.[86]

Differential Considerations

Considerations in the differential diagnosis include the entities previously mentioned regarding proteinuria, including nephrotic syndrome and urinary tract infection.

Management and Disposition

Management includes restriction of fluid and salt intake and sometimes use of diuretics. A child with significant hypertension, congestive heart failure, or uremia requires hospitalization for inpatient management. Significant hypertension should be treated as outlined in the section on hypertension.

Children with mild symptoms in whom good follow-up can be ensured can be managed on an outpatient basis.

Nephrotic Syndrome

Perspective

Nephrotic syndrome is characterized by hypoproteinemia, proteinuria, and edema. Primary nephrotic syndrome applies to diseases limited to the kidney; renal biopsy is used to stratify patients and to determine therapeutic and prognostic decisions. Secondary nephrotic syndrome results from systemic illnesses such as PSGN.

Principles of Disease

From 2 to 7 cases of nephrotic syndrome per 100,000 children are discovered each year.[82] Boys are affected twice as often as girls are, but the distribution equalizes by adulthood. Primary nephrotic syndrome occurs more commonly in children younger than 5 years, and secondary nephrotic syndrome occurs more often in older children. Ninety percent of affected children have the primary disease; 85% have minimal change nephrotic syndrome, 10% focal sclerosis, and 5% mesangial proliferation (referring to the thin membrane-supporting capillaries surrounding the tubule of nephrons).

The etiology of primary nephrotic syndrome is thought to be idiopathic, but various theories involving bacterial or viral infections, allergic reactions (pollens, poison ivy), or drug ingestions (heroin, mercury) have been investigated.[82]

Clinical Features

Characteristics of nephrotic syndrome include edema, hypoalbuminemia, proteinuria, and hyperlipidemia. The onset of edema may be insidious, beginning with periorbital edema. As weight increases, pants and shoes may not fit. The edema progresses, but the child usually does not appear ill unless pulmonary edema or ascites is present. Other features may include anorexia, nausea, and vomiting secondary to edema of the intestine. Hypertension, hematuria, or oliguria may be present. Acute renal failure is rare in primary nephrotic syndrome.

www.ketabpezeshki.com 66485457-66963820

Nephrotic children also are at risk for thrombosis, with a reported rate of thromboembolic complications of 2%.[88] Renal veins are particularly vulnerable to thrombosis, as characterized by flank pain, hematuria, and worsening renal function. Nephrotic children should not undergo punctures to deep vessels because of this risk of thrombosis.

Children with nephrotic syndrome taking corticosteroids also are at greater risk for side effects of corticosteroid use even at dosages as low as 1 mg/kg per 48 hours.[89] Acute mood changes, from depression to mania, are associated with use of steroids. Irritability, excessive crying, and sleeping difficulties can result.

Because of steroid therapy and decreased levels of immunoglobulins, nephrotic children are at risk for bacterial infections, such as from *E. coli* and *Streptococcus pneumoniae*.

Diagnostic Strategies

Proteinuria in nephrotic syndrome is defined as excretion of more than 3.5 g of protein per 1.73 m^2 per 24 hours or more than 50 mg/kg per 24 hours. This corresponds to 3+ or 4+ on the dipstick reading. Specific gravity may be high because of the proteinuria. Microscopic hematuria also may be present. Total serum protein usually is low at 4.5 to 5.5 g/dL, and serum albumin is less than 2 g/dL.

Hyperlipidemia may occur because of the increased serum cholesterol. Hyponatremia may be present, but other electrolytes usually are normal. If an elevated cholesterol level is present, the lowered sodium level may be a combination of true hyponatremia and pseudohyponatremia. BUN and creatinine concentrations usually also are normal, and hemoglobin and hematocrit levels may be elevated because of hemoconcentration.

Chest radiographs sometimes show pleural effusions or pulmonary edema. The heart appears normal or small because of hypovolemia. An abdominal radiograph may reveal ascites, and ultrasonography may show a renal abnormality.

Renal biopsy is important for diagnostic and therapeutic decisions and should be performed in older children or in patients with evidence of hematuria, elevated BUN, or persistent hypertension or in whom the renal dysfunction fails to respond to steroids.

Differential Considerations

Other renal diseases that cause edema include glomerulonephritis and renal failure. A vasculitis or acute thrombosis of the renal vessels also must be considered. Gastrointestinal disorders that produce hypoproteinemia include cirrhosis, cystic fibrosis, and protein-losing enteritides.

Management

Despite the edema, children with signs of hypovolemia or shock need to be resuscitated with crystalloid. Hypertension may result from the intrinsic disease; prompt recognition and treatment of this condition are important.

After consultation with a pediatric nephrologist, patients between 12 months and 5 years of age with no gross hematuria and no large loss of protein or complement can be treated with corticosteroids. After the initial evaluation is completed, including a tuberculin test, prednisone at 2 mg/kg per 24 hours orally, divided two or three times a day, can be initiated. Relapses or steroid resistance may necessitate a second course of steroids.[82]

Diuretics such as furosemide, 1 to 2 mg/kg per 24 hours orally or intravenously in divided doses, may be necessary if respiratory distress or significant ascites is present. Salt restriction may be required. Fluid intake should be restricted only if edema is present despite salt restriction or if the child exhibits hyponatremia because of an impaired ability to excrete excess water.

The relatively immunocompromised status of nephrotic children increases the risk of infection. A fever or signs of peritonitis must be investigated thoroughly. A paracentesis should be performed and fluid sent for cell and differential counts, Gram's stain, and culture. Hospital admission and empirical antibiotic therapy with agents with activity against *S. pneumoniae* and *E. coli* are appropriate.[82]

Disposition

Hospitalization should be considered for newly diagnosed patients for initial evaluation, treatment, and education of both the child and the parents. Patients with signs of shock or respiratory distress should be admitted to the hospital after initial stabilization. Other patients with suspected bacterial infections, peritonitis, edema refractory to therapy, or evidence of renal insufficiency also should be hospitalized.

Acute Renal Failure

Perspective

Acute renal failure results from impaired glomerular filtration rate. Blood pressure, acid-base balance, removal of nitrogen waste, and fluid management may be affected. The incidence of acute renal failure is unknown, but large children's hospitals may see 30 to 50 new cases each year.

Principles of Disease

Acute renal failure can be divided into three categories: prerenal, which involves decreased renal perfusion; renal (intrarenal), which is caused by parenchymal damage; and postrenal, which involves obstruction of the urinary tract (Box 174-3).

Causes of prerenal failure include hypovolemia resulting from a variety of factors (e.g., dehydration, burns, hemorrhage), shock (e.g., sepsis, anaphylaxis), and congestive heart failure (e.g., decreased cardiac output). Obstruction of the renal artery or thrombosis of the renal vein also can cause acute renal failure.

Intrarenal causes involve damage to the nephron. Glomerular damage most commonly results from PSGN. Systemic lupus erythematosus, HUS, and sepsis with hypoperfusion are systemic causes of renal failure. Tubular damage can result from heavy metal poisonings or hemoglobin-myoglobin in the tubules from a crush injury, burn, or hemolytic crisis. Cases of acute renal failure in dehydrated children after NSAID use have been reported.[90]

Postrenal failure resulting from an obstruction in the urinary tract may be caused by infection, tumor, renal stones, or posterior urethral valves. Bilateral obstruction of the kidneys usually is necessary for renal failure to occur.

Clinical Features

A child with acute renal failure accumulates nitrogen wastes shown by an increase in BUN and serum creatinine levels. A decrease in urine output is sometimes seen. A urinary output of 1 mL/kg per hour usually is considered adequate, but the output may be lower if the patient is dehydrated. Nephrotoxic agents such as certain aminoglycosides can actually increase the urinary output because of renal tubular damage, but BUN and serum creatinine levels are still elevated.

Acute renal failure can result in life-threatening complications that must be recognized and treated promptly. These include severe hyperkalemia, pulmonary edema or fluid overload,

www.ketabpezeshki.com 66485457-66963820

Box 174-3 Etiology of Acute Renal Failure in Children

Prerenal
Decreased intravascular volume or dehydration

- Nephrolithiasis or tumor
- Posturethral valves
- Intra-abdominal tumor obstructing urinary flow
- Infection

Renal vein thrombosis

hypertensive encephalopathy, septic shock from renal obstruction and infection, and seizures from metabolic abnormalities or encephalopathy.[91]

Diagnostic Strategies

Preliminary laboratory tests should include CBC; determination of electrolyte, calcium, phosphorus, BUN, and serum creatinine levels; and urinalysis with microscopy and culture. Diagnostic studies such as ASO titer (for acute PSGN), C3 complement (for lupus), total serum albumin, cholesterol, and albumin-to-globulin ratio (for nephrotic syndrome and cirrhosis) may be obtained. RBC casts in the urine indicate glomerulonephritis. WBC casts indicate infection as an etiologic disorder, whereas hyaline casts suggest dehydration or acute tubular necrosis.[92]

Ultrasonography is the imaging modality of choice for the preliminary evaluation of obstructive causes of renal failure. Non–contrast-enhanced CT urography also can readily identify the site of obstruction and avoids the use of nephrotoxic radiocontrast material. Voiding cystourethrography shows extrinsic pressure on the bladder by posterior urethral valves.

Differential Considerations

Significant dehydration can result in temporary decreased urine output. Renal markers are typically increased, with BUN rising more than creatinine. After hydration and repletion of intravascular volume, urine output should improve and the elevated BUN and creatinine concentrations should resolve. Processes that can result in retention of fluids with associated renal failure include liver disease and decreased cardiac output.

Management

The initial management of a child with acute renal failure depends on the clinical evaluation. If hypovolemia resulting from dehydration or blood loss is thought to be the cause of the renal failure, immediate rehydration is necessary. A bolus of 20 mL/kg of crystalloid should be given to prevent possible progression to acute tubular necrosis. If no urinary response is obtained after two boluses of crystalloid, diuretics may be useful in the euvolemic patient. Furosemide, 1 mg/kg per dose every 2 to 6 hours intravenously, may be tried if there is no evidence of obstruction. Bumetanide, 0.015 to 0.1 mg/kg per dose every 6 to 24 hours intravenously (maximum of 10 mg per 24 hours), can be useful if furosemide has no effect. Mannitol, 0.75 g/kg per dose every 6 hours intravenously, also may be helpful but because of the resultant increased urine flow is contraindicated if there is evidence of obstruction.

If the child is considered euvolemic and has no urine output despite diuretic therapy, renal-dose dopamine should be initiated (2 to 5 µg/kg per minute). Consultation with a nephrologist should be obtained.[91]

If hypertension with encephalopathy develops, a controlled 10 to 20% reduction in blood pressure should be achieved by use of nitroprusside or other intravenous blood pressure agents. Oral medications, such as nifedipine and captopril, are useful but are associated with the risk of a precipitous drop in blood pressure. Overaggressive reduction in blood pressure can result in hypoperfusion of central target organs, such as the brain, heart, and kidneys, that have become accustomed to higher perfusion pressures. Further discussion of hypertensive emergencies and treatment can be found in Chapter 84.

Hyperkalemia can result in cardiac dysrhythmias. Potassium levels higher than 6.5 mEq/L may cause changes on the electrocardiogram such as peaked T waves and, if significant, widened QRS complexes. Hyperkalemia with resultant electrocardiographic changes, such as loss of the p wave or widened QRS complex, should be treated with calcium gluconate, 10% solution, 0.5 mL/kg per dose given intravenously over 5 minutes (maximum dose, 20 mL [2 g]). Calcium alters the action potentials of the cardiac cells, thereby decreasing the risk of arrhythmias. The calcium dose may be repeated in 5 minutes.

Sodium bicarbonate, 1 to 2 mEq/kg per dose intravenously every 4 hours, also can be administered. The resultant alkalosis helps move the potassium intracellularly by exchanging H^+ for K^+. Continued therapy with sodium bicarbonate should be administered in conjunction with pediatric nephrology services because of the risk of increasing volume load with repetitive dosages of sodium. Potassium-binding agents such as sodium polystyrene sulfonate (Kayexalate) are administered orally or rectally and exchange Na^+ for K^+ in a 1:1 ratio.

Glucose (50% dextrose in water for ≥3 years old and 25% dextrose in water for ≤2 years old), 0.5 to 1 g/kg, should be given along with regular insulin (1 unit for every 4 g of glucose administered). The insulin temporarily shifts the potassium intracellularly.

Nebulized albuterol also can be used to shift potassium temporarily into the cells and lowers serum potassium by 1 to 1.5 mEq/L during 30 minutes.[93] Severe cases and those associated with renal failure should be immediately referred to a pediatric nephrologist for emergent dialysis.[91]

Acute renal failure may lead to seizures caused by either hypertensive encephalopathy or a metabolic derangement, most commonly hyponatremia resulting from dilution of the sodium by free water. Intractable hyponatremic seizures may rarely necessitate the use of hypertonic saline (3% sodium chloride). Each 1 mL/kg of 3% sodium chloride increases the serum sodium by approximately 1 mEq/L. A child with hyponatremic symptoms, such as seizures, will often improve after receiving 3 to 5 mL/kg of 3% sodium

www.ketabpezeshki.com 66485457-66963820

chloride. Once the seizures have ceased, sodium correction should then continue more slowly to avoid central pontine myelinolysis. Recommendations are to correct the sodium no faster than 10 to 12 mEq/L in the first 24 hours and not more than 18 mEq/L in the first 48 hours.

Normal saline (0.9%) is relatively hypertonic compared with serum and therefore also may be helpful in correcting the hyponatremia. Water restriction along with the administration of saline usually is only a temporary treatment because many of these hyponatremic patients ultimately require dialysis.

Sodium bicarbonate will correct a persistent metabolic acidosis and maintain pH 7.1 or higher and a serum bicarbonate level of 15 mEq/L. The base deficit can determine the amount of bicarbonate needed:

$$\text{Base deficit} = [0.6 \times (\text{body weight in kg}) \times (\text{desired bicarbonate level} - \text{observed level})] \div 2$$

Half the replacement is given in the first 3 hours, with the remainder given during the next 24 hours.

Hemodialysis or peritoneal dialysis may be indicated for refractory fluid overload associated with hypertension, congestive heart failure, pulmonary edema, severe hyperkalemia, hyponatremia or hypernatremia, metabolic acidosis, myoglobinuria resulting from burn or crush injuries, or HUS with hemoglobinuria or encephalopathy.[91]

Disposition

All children with acute renal failure should be admitted to the hospital. Any child with signs of congestive heart failure, pulmonary edema, significant hyperkalemia, or acidosis should be admitted to a monitored bed.

Hypertension

Perspective

Hypertension is defined as a systolic or diastolic blood pressure higher than 2 SDs above the mean for the age and sex of the patient (Table 174-1). This diagnosis requires three or more accurate blood pressure measurements during the course of several weeks. A correct cuff size should be chosen (i.e., the air bladder should cover 80 to 100% of the circumference and two thirds of the length of the upper arm).[85] It is recommended that all children receive yearly blood pressure measurements starting at the age of 3 years.[85] A child who is in pain or agitated may have falsely elevated blood pressure readings.

Principles of Disease

Hypertension occurs throughout childhood in both boys and girls. It probably occurs more often in African American children than in white children, just as in the adult population. Predisposing factors include obesity, physical inactivity, and a strong family history. Metabolic syndrome, a combination of insulin resistance, hypertension, and hyperlipidemia, may affect up to 50% of overweight adolescents.[94]

Just as in adulthood, primary or essential hypertension is unrelated to a second systemic disease. Children diagnosed with primary hypertension are more likely to become adults with hypertension. Secondary hypertension results from endocrinologic, cardiac, neurologic, or other factors, such as exposure to certain drugs or poisons (Box 174-4). In children with significant hypertension, the underlying cause usually is renal (as in glomerulonephritis) or renovascular.

Table 174-1 Blood Pressure Limits in Children

	BLOOD PRESSURE: UPPER LIMIT	
AGE	Systolic	Diastolic
0-2 years	110 mm Hg	65 mm Hg
3-6 years	120 mm Hg	70 mm Hg
7-10 years	130 mm Hg	75 mm Hg
11-15 years	140 mm Hg	80 mm Hg

Clinical Features

There are a variety of clinical presentations of hypertension in children. First, asymptomatic or mildly symptomatic hypertension may show up in routine vital signs measured in children evaluated in the ED for unrelated illnesses. When asked, these children may complain of headaches, abdominal pain, irritability, or nosebleeds. Personality changes and difficulties in school are sometimes noted.

Hypertension in young children may also be manifested as severe elevations in systolic or diastolic blood pressures (younger than 10 years: systolic blood pressure 160 mm Hg or higher, diastolic blood pressure 105 mm Hg or higher; older than 10 years: systolic blood pressure 170 mm Hg or higher, diastolic blood pressure 110 mm Hg or higher) but without signs of end-organ damage. These cases are also important to recognize as close follow-up with a primary care physician will be important.

In children experiencing a hypertensive emergency, clinical signs of end-organ damage will be present. A severe elevation in blood pressure is associated with acute neurologic changes or encephalopathy, pulmonary edema, myocardial ischemia, or proteinuria. The electrocardiogram may show signs of ischemia or ventricular hypertrophy. Chest radiography may reveal cardiomegaly or pulmonary edema. Hypertensive emergencies require prompt recognition and treatment. However, overaggressive treatment of long-standing hypertension can produce relative hypotension, leading to worsening neurologic deficit.

Hypertensive encephalopathy symptoms include headache, vomiting, altered mental status, visual disturbances (including blurry vision and diplopia), and seizures or stroke. Papilledema, decreased retinal venous pulsations, and cranial nerve palsies may be found on examination. The diagnosis is confirmed when the symptoms and signs subside rapidly after the blood pressure is lowered. Headache alone, without any other associated symptoms or signs, generally is not considered to represent a hypertensive emergency.

Diagnostic Strategies

In addition to a thorough history and physical examination, laboratory and radiologic studies performed in the ED often can determine both the cause of the hypertension and whether a hypertensive emergency exists (Box 174-5).

Box 174-5 Diagnostic Evaluation in Hypertensive Emergencies* in Children

History of medications or drugs, or family history of cardiovascular disorders
Symptoms of severe headache or chest pain
Physical examination focused on acute neurologic changes, funduscopic abnormalities, pulmonary edema
Urinalysis for significant protein
Chest radiograph for cardiomegaly or congestive heart failure
Electrocardiogram for ventricular hypertrophy

Primary or Secondary Cause?
Laboratory and Radiologic Tests to Consider

Urinalysis and urine culture
Urine catecholamine assay
Complete blood count with platelet count
Blood smear
Sodium, potassium, chloride, carbon dioxide, calcium, phosphorus, magnesium, uric acid measurement
Blood urea nitrogen and creatinine determinations
Serum C3 complement assay, antistreptolysin O titer, antinuclear antibody assay
Plasma renin level
Computed tomography urography or intravenous pyelography
Voiding cystourethrography
Renal ultrasound scan
Renal arteriography

*Evidence of end-organ damage.

Differential Considerations

Any situation that causes undue agitation or pain in a child can cause a transient rise in blood pressure. Therefore, the diagnosis of hypertension in a pediatric patient should be based only on carefully measured blood pressures in a nonagitated child during several weeks. Secondary hypertension is more likely in symptomatic younger children, especially those without a strong family history.

Other disorders with presentations similar to that of hypertensive encephalopathy include meningitis, brain tumor, intracerebral hemorrhage, stroke, and uremia. These conditions, however, generally produce only a mild increase in the systolic blood pressure[95]; CT or lumbar puncture also can help identify these other disorders.

Management

The management of hypertensive emergencies also is discussed in Chapter 84. When a child with severe hypertension is seen in the ED, questions should focus on a history of hypertension, urinary tract infections, hematuria, edema, or umbilical artery catheterization. A history of joint pain or swelling, palpitations, weight loss, flushing of the skin, or drug ingestion or a family history is important to ascertain.

A physical examination emphasizing the central nervous system and cardiopulmonary system is indicated. Examination of the fundus may reveal papilledema or hemorrhages. Signs of congestive heart failure or a difference in the upper and lower extremity blood pressures should be noted. Coarctation of the aorta may be manifested with a difference in either blood pressure or palpable pulse between the upper and lower extremities. A renal cause of the hypertension may be revealed by the presence of peripheral edema or palpable kidneys. An abdominal or flank bruit suggests renovascular hypertension. Initial laboratory tests should include a CBC, electrolyte values, BUN and creatinine concentrations, urinalysis, urine culture, chest radiograph, and electrocardiogram.

A child in whom clinical findings are consistent with a hypertensive emergency (e.g., acute end-organ damage as found by physical examination, laboratory, or radiologic results) should have intravenous access and be monitored with continuous blood pressure readings; an arterial catheter is preferable. The goal of therapy is to reduce the mean arterial blood pressure by 10 to 20% during several minutes to hours, depending on the nature of the emergency. Headache and vomiting require blood pressure control during several hours, whereas intracranial bleeding or herniation requires reduction in several minutes. Beta-blockers are contraindicated in patients with decreased cardiac output and clinical signs of congestive heart failure. Oral nifedipine is contraindicated in patients with signs of end-organ damage, such as intracerebral bleeding, because of the inability to control the amount of blood pressure reduction. For avoidance of overaggressive treatment and resultant relative hypotension, medications that can be controlled by intravenous infusions are preferred (Table 174-2).

Severe hypertension without evidence of end-organ damage, as stated earlier, is also important to recognize. Antihypertensives should be started or restarted for these patients to prevent end-organ sequelae. Angiotensin-converting enzyme inhibitors or calcium channel blockers are useful as first-line agents and usually are well tolerated. The child may be observed for a few hours after

Table 174-2 Medications Used in Hypertensive Emergencies

MEDICATION	DOSE	TIME TO REPEAT DOSE	DURATION OF EFFECT	SIDE EFFECTS
Nitroprusside	0.3-0.5 μg/kg/min IV (max. 10 μg/kg/min)	30-60 minutes	During infusion	Headache, abdominal pain, chest pain, gastrointestinal upset, seizures, thiocyanate and cyanide toxicity*
Hydralazine†	0.1-0.2 mg/kg IV (max. 20 mg) slowly during 15 minutes	10-20 minutes	4-12 hours	Tachycardia, skin flushing, headache, vomiting, diarrhea, hypotension
Labetalol‡§	May bolus 0.2-1 mg/kg IV (max. 20 mg), then 0.4-1 mg/kg/hr IV (max. 3 mg/kg/hr)	10 minutes	6 hours, but variable	Gastrointestinal upset, headache, sedation
Esmolol‖¶**	Load 100-500 μg/kg IV during 1-2 minutes, then maintenance 25-100 μg/kg/min	10 minutes	During infusion	Similar to labetalol
Phentolamine	0.1 mg/kg/dose IV (max. 5 mg)	30 minutes	30-60 minutes	Tachycardia, abdominal pain

*Avoid in pregnancy.
†Use with caution in renal patients.
‡Avoid in asthma, pulmonary edema, and heart block.
§Avoid in second and third trimesters of pregnancy.
‖With inadequate response, readminister loading dose or increase maintenance dose by 25-50 μg/kg/min every 5-10 minutes.
¶Usual maintenance range: 50-500 μg/kg/min.
**Morphine may increase esmolol levels.
Note: Diazoxide is no longer recommended because of the associated potential for an acute drop in blood pressure.

administration of the medication for evaluation of effectiveness or complications. With no evidence of acute end-organ damage, the child can be safely discharged home, assuming that good follow-up can be ensured.

Children with mildly elevated blood pressures (5 to 10 mm Hg above normal) unrelated to the ED visit require repeated blood pressure measurements before treatment of hypertension is begun. If the blood pressure is moderately elevated and the patient is asymptomatic, appropriate management consists of discharge home for outpatient workup of the hypertension and follow-up with the patient's primary care physician for monitoring of blood pressure values. Thiazide diuretics or beta-blockers may be started at low doses.

Disposition

A child with evidence of a hypertensive emergency (i.e., acute end-organ damage) must be hospitalized for evaluation and care in a monitored bed. A child with significantly elevated blood pressure but without evidence of end-organ damage can be discharged home if good follow-up can be ensured.

Henoch-Schönlein Purpura

Perspective

Henoch-Schönlein purpura is an immunoglobulin A–mediated systemic vasculitis involving the small blood vessels supplying the skin, gastrointestinal tract, and joints.[96] The peak incidence is between 4 and 7 years of age, with an overall occurrence rate of 13.5 episodes per 100,000 children annually.

Principles of Disease

Immune complex deposition results in a systemic vasculitis, with up to 33% of patients experiencing recurrences.[97] Approximately 50% of affected children have a history of previous upper respiratory tract infection, and as many as 75% have group A beta-hemolytic streptococci cultured from the oropharynx. Other theorized predisposing factors include exposure to cold weather, certain foods, drugs, and insect bites. Varicella-zoster virus, *Mycoplasma* species, parvovirus, *Campylobacter enteritidis,* parvovirus B19, and Epstein-Barr virus also have been implicated.

Clinical Features

The hallmark of Henoch-Schönlein purpura is a palpable, purpuric, or petechial rash most prominent on the lower extremities, starting at the lateral malleoli and extending to the buttocks. The cutaneous manifestations are the initial presenting complaint in 50% of patients. Arthralgia or arthritis occurs commonly[98] and usually involves the knee and ankle joints. Gastrointestinal manifestations are present in up to 65% of patients, with the most common symptom being dull periumbilical pain resulting from bleeding into the intestinal wall.[98] The abdominal pain typically occurs concurrently with or immediately after onset of the rash; however, in up to 25 to 50% of patients, abdominal pain or arthritis can be the initial complaint.[98,99] A self-limited glomerulonephritis manifested by hematuria develops in 25 to 50% of children. This condition progresses to chronic renal insufficiency in less than 1% of these patients. Children presenting with acute renal failure, nephrotic syndrome, or hypertension are more likely to have unfavorable outcomes, such as chronic renal failure.[92] Testicular involvement occurs in up to 35% of patients; they may present with severe scrotal edema that resembles acute testicular torsion.

Diagnostic Strategies

There are no specific tests to confirm the diagnosis of Henoch-Schönlein purpura, and recognition of the disorder can be difficult if the classic rash is absent at the time of presentation. Screening tests such as urinalysis, BUN and serum creatinine determinations, CBC, and coagulation studies may be needed to rule out other pathologic conditions. Ultrasound findings in patients with abdominal pain typically include evidence of intraluminal hematomas and duodenal wall thickening.[100] Intussusception also may complicate the disease.

Differential Considerations

Considerations in the differential diagnosis include meningococcemia, Rocky Mountain spotted fever, intussusception, trauma,

www.ketabpezeshki.com 66485457-66963820

appendicitis, thrombotic thrombocytopenic purpura, juvenile rheumatoid arthritis, bacterial endocarditis, systemic lupus erythematosus, kidney stones, and primary renal disease.

Management

Treatment of Henoch-Schönlein purpura remains controversial because most cases resolve spontaneously and do not require therapy. NSAIDs can be used to treat joint pain, but close attention must be paid to renal function. Corticosteroids have been used to treat severe renal or gastrointestinal involvement. A meta-analysis of data on the use of steroids for Henoch-Schönlein purpura found these agents to be effective in reducing the time to resolution of abdominal pain and to reduce the odds for development of persistent renal disease.[101] Prednisone or methylprednisolone pulse therapy has shown some benefit, but an acute surgical process should be excluded before initiation of steroids.[100] Therapy for patients with severe renal involvement also includes intravenous immune globulin, although promising results also have been seen in patients with severe abdominal pain.[102] Other treatment options for patients with severe Henoch-Schönlein purpura–related nephropathy include early treatment with oral immunosuppressants[103] and possibly the use of methylprednisolone and urokinase pulse therapy.[104] A nephrologist should be consulted for appropriate management of patients with renal involvement, and good follow-up must be ensured.

Disposition

Patients with only the skin manifestations of Henoch-Schönlein purpura usually can be discharged home with symptomatic therapy for the joint pain and malaise. An NSAID or acetaminophen usually is sufficient, but close follow-up should be ensured. Patients with abdominal pain or renal involvement should be admitted for further evaluation and treatment.

Hemolytic-Uremic Syndrome

Perspective

HUS continues to be one of the most common causes of acute renal failure in children.[105] It most commonly affects infants and children, with a mean age at presentation of 3 years, but is rare after 5 years of age. There is no sex predilection, and outbreaks can be sporadic or epidemic, especially when the disorder is related to the most common offending agent, verotoxin produced by *E. coli* serotype O157:H7. Transmission is through person-to-person contact and also exposure to contaminated food, such as unpasteurized dairy products or beef.[106] Other causes of HUS include *Shigella* organisms, *S. pneumoniae, Aeromonas,* human immunodeficiency virus, and drugs; hereditary, familial, and idiopathic forms are recognized as well.

Principles of Disease

Renal compromise is the result of injury to the renal vascular endothelium induced by viral or bacterial agents or the toxins released. Microangiopathic hemolytic anemia then results from injury to the RBCs by fibrin strands along the narrowed blood vessels. Platelets, complement, and fibrin also are deposited in the glomerular lumen, leading to a decrease in glomerular filtration rate and renal failure.

Clinical Features

Patients with HUS present with watery diarrhea, crampy abdominal pain, and occasionally fever. From 2 to 3 days after onset of symptoms, patients experience increased abdominal pain with bloody stools, the latter developing in up to 89% of patients by day 5.[107] Other pathologic features may include toxic megacolon, ischemic colitis, intussusception, perforation, or delayed colonic stricture. After the prodromal gastroenteritis, patients experience sudden onset of hemolytic anemia, thrombocytopenia, and acute renal insufficiency, with possible progression to renal failure. In a meta-analysis published in 2003, death or end-stage renal disease occurred in 12% of cases of diarrhea-associated HUS, and 25% of survivors demonstrated long-term renal sequelae.[108] Pancreatic insufficiency resulting in insulin-dependent diabetes mellitus also has been reported. There are reports of HUS occurring in association with urinary tract infection as well.[109]

Central nervous system irritability may develop and may result in seizures in 40% of patients. Hypertension occurs in up to 50% of patients and may contribute to the development of encephalopathy. HUS recurrences have been associated with a 30% mortality rate.

Diagnostic Strategies

Leukocyte counts and C-reactive protein levels were found to be significantly higher in patients with toxin-producing *E. coli* O157:H7.[106] The peripheral blood smear shows microangiopathic changes such as teardrop cells, helmet cells, microspherocytes, and burr cells. WBC counts may be elevated, and the platelet count may be less than 50,000/µL. The hemoglobin can be as low as 5 g/dL as a result of the rapid hemolysis that occurs.

Differential Considerations

Considerations in the differential diagnosis of HUS include thrombocytopenic thrombotic purpura, ulcerative colitis, intussusception, and other causes of acquired hemolytic anemia.

Management

Supportive therapy and early peritoneal dialysis account for the reduction in current mortality rates to less than 5%. Patients should be rehydrated; however, it is important not to overload these children with fluids. Hyperkalemia is common and should be treated with sodium bicarbonate, calcium gluconate or chloride, dextrose and insulin, and sodium polystyrene sulfonate (Kayexalate). Patients with severe hyperkalemia, hyperphosphatemia, or severe metabolic acidosis require dialysis.

Packed RBCs (5 mL/kg during 4 hours) typically are administered if the hemoglobin falls below 6 g/dL. Platelet transfusions are required only for life-threatening bleeding or before an invasive procedure. Hypertension is responsive to calcium channel blockers, labetalol, captopril, or nitroprusside in refractory cases. Seizures typically respond to benzodiazepines and phenytoin; however, if they are secondary to hyponatremia, treatment with 3% saline (4 mL/kg) may be indicated. Treatment of the colitis itself also is supportive only because antimotility agents may lead to toxic megacolon. To date, no randomized trials have been conducted to show the effectiveness of antibiotics for the prevention of the development of HUS. Accordingly, because antibiotics may enhance the release of verotoxin from the bacteria, antibiotics should be avoided.[110] Hyperglycemia, ketonemia, and acidosis secondary to pancreatic islet cell necrosis are managed with insulin therapy.

Idiopathic HUS may be treated with plasmapheresis, especially if neurologic involvement is present. If this therapeutic measure is unsuccessful, renal transplantation may be required. Unfortunately, idiopathic HUS also can recur in the transplanted kidney.

www.ketabpezeshki.com 66485457-66963820

Disposition

Patients with HUS require hospital admission, and consultation with a pediatric nephrologist and a urologist should be arranged. Early dialysis and supportive therapy result in return to baseline renal function in up to 90% of patients with acute renal failure.

KEY CONCEPTS

Priapism

- In low-flow priapism, cavernosal aspiration plus irrigation has been effective when it is performed within the first 48 hours, and preferably within a few hours, of symptom onset. Phentolamine, phenylephrine, ephedrine, or 1 : 1,000,000 epinephrine often is added to the irrigation solution used in performing corporal aspiration.

Phimosis and Paraphimosis

- Steroid cream is first-line therapy for phimosis. In paraphimosis involving vascular compromise of the glans penis, a dorsal slit procedure may be necessary.

Testicular Torsion

- Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, a necrotic, gangrenous testis. Testicular salvage rates are time dependent, with a 96% success rate if detorsion is performed less than 4 hours after symptom onset; with more than a 24-hour delay in time to treatment, the success rate decreases to less than 10%.

Varicoceles

- Left-sided varicoceles account for 85 to 95% of the cases. Intra-abdominal disease should be suspected in cases of right-sided varicoceles because these usually are caused by inferior vena cava thrombosis or compression of this vessel by tumors.

Urinary Tract Infections

- In children younger than 2 years, a urinalysis alone is inadequate to rule out urinary tract infections because this study yields false-negative results in as many as 10 to 50% of patients.

Hematuria

- Hematuria is common in children with causes as simple as a urinary tract infection to more complicated conditions, such as glomerulonephritis or Henoch-Schönlein purpura.

Renal Failure

- Renal failure thought to be secondary to dehydration should be corrected immediately with a bolus of normal saline, with repeated laboratory studies showing an improvement in renal function.

Hypertension

- Other significant clinical conditions, such as meningitis, brain tumor, intracerebral hemorrhage, stroke, and uremia, may be manifested similar to a hypertensive emergency; these conditions, however, in general have only mildly elevated blood pressure.

Chapter 175

Neurologic Disorders

David H. Rubin, Dina Halpern Kornblau, Edward E. Conway, Jr., and Stuart M. Caplen

PERSPECTIVE

Many acute neurologic manifestations of disease that precipitate a visit to the emergency department (ED), such as seizure, vertigo, ataxia, and headache, appear in both adults and children. However, associated signs and symptoms and diagnostic considerations in children are unique and markedly different from those in the adult population. Moreover, bacterial meningitis, once a predominantly pediatric disease, is now mainly a disease of adults; yet it remains imperative to recognize subtle signs and symptoms of this lethal disease in infants and young children.

ACUTE BACTERIAL MENINGITIS

Perspective

Despite advances in medical care, acute bacterial meningitis (ABM) remains a potentially life-threatening emergency. Nationwide mortality rates for treated cases are 20 to 30% in neonates and adults and 2% in infants and children.[1] With the recommendation in 1991 that all infants, starting at 2 months of age, receive the conjugated vaccine against *Haemophilus influenzae* type b, the incidence of bacterial meningitis caused by this organism has been reduced in children by more than 99%. However, recent data show that the highest incidence is still found in children younger than 2 months.[1,2] Even with the best care, 10 to 30% of all survivors of bacterial meningitis of all types demonstrate persistent, functionally important disabilities.[3,4] These include hearing deficits, seizures, learning and behavioral problems, and cognitive impairments.

Neonates

Group B streptococci account for more than three quarters of the cases of neonatal meningitis; *Escherichia coli* (and other coliforms), *Listeria monocytogenes, Streptococcus pneumoniae, Neisseria meningitidis,* and *H. influenzae* are responsible for another one fourth of cases.[2] The incidence of early-onset group B streptococcal disease has declined as a result of intrapartum prophylaxis. However, late-onset disease (after 7 days of life) has not. *Staphylococcus epidermidis*, *Staphylococcus aureus*, *S. pneumoniae*, *N. meningitidis*, group D streptococci, *Ureaplasma urealyticum*, *H. influenzae* type b, and nontypable strains are less common pathogens in neonatal infection. *L. monocytogenes* rarely is the agent of meningitis in neonates but is important because of its prevalence within some immigrant groups, its association with unpasteurized dairy products, and its resistance to cephalosporins.[5]

Infants and Children

Beyond the neonatal period, in the United States, *S. pneumoniae, N. meningitidis,* and *H. influenzae* account for 90% of the documented cases of ABM.[2] Unusual pathogens include *Salmonella* species, *Campylobacter* species, *L. monocytogenes*, group G streptococci, *Francisella tularensis,* group B beta-hemolytic streptococci, and several anaerobic organisms.[1,2] Recent advances involving the heptavalent pneumococcal conjugate vaccine (PCV7), recommended for all children younger than 2 years, have dramatically reduced the number of cases of bacterial meningitis caused by invasive pneumococcal disease.[6] It is anticipated that the newly released 13-valent pneumococcal conjugate vaccine (PCV13) will have an even greater impact on the reduction of invasive pneumococcal disease.[7]

Principles of Disease

Host factors influence the degree of susceptibility to meningitis. Newborn infants younger than 1 month, particularly those born prematurely, are at greatest risk for ABM owing to their immunologic immaturity. Other groups predisposed to ABM include males, Native Americans, African Americans, malnourished persons, indigent urban dwellers, daycare center attendants, patients with compromised immune status (from sickle hemoglobinopathies, acquired immunodeficiency syndrome [AIDS], asplenia, renal disease, hepatic disease, diabetes mellitus, or dysgammaglobulinemia), and those undergoing immunosuppressive treatment, including corticosteroid therapy.

Bacterial meningitis is thought to result from infection of the respiratory tract, development of bacteremia, invasion of the meninges, and inflammation of the meninges and brain.[5] Invasion of the meninges by bacterial pathogens is facilitated by mechanical disturbances. These include recent neurosurgical procedures, such as ventriculoperitoneal shunt placement and lumbar puncture, and skull fracture with a persistent cerebrospinal fluid (CSF) leak. Congenital or developmental central nervous system (CNS) abnormalities also predispose affected patients to bacterial seeding of the CNS. These include intracranial cysts and epidermoid or dermoid tumors, often with an associated congenital dermal sinus track.

For ABM to occur, organisms must gain entrance into the subarachnoid space. On rare occasions, this occurs as a direct extension from a contiguous focus, such as sinusitis, mastoiditis, or otitis media. In a majority of cases, the bacterial organism gains access to the bloodstream and hematogenously seeds through inflamed capillaries within the choroid plexus. Most cases of ABM follow a progression of events. After exposure and nasopharyngeal

www.ketabpezeshki.com 66485457-66963820

colonization, invasion of the blood occurs. The organism can be recovered from the bloodstream in up to 90% of patients with CSF culture–proven bacterial meningitis.

If bacteria gain entrance into the subarachnoid space, they replicate. Microbial traversal of the blood-brain barrier occurs by microbial interactions with host receptors. Each organism may gain entry in a specific manner. For example, *E. coli* penetration into the brain involves binding to and invasion of the human brain microvascular endothelial cells, which are part of the blood-brain barrier.[8] Host inflammatory mediators and cytokines, including interleukin-1, tumor necrosis factor, and platelet-activating factor, may also be produced and secreted by CNS macrophages and endothelial cells. As a result of an inflammatory response, vascular and parenchymatous cerebral changes occur. These include vasculitis, microthrombus formation, occlusion of venous sinuses, reduced blood flow, increased permeability of the blood-brain barrier, increased intracranial pressure (ICP), diffuse cerebral edema, and intracerebral hemorrhage. Changes involved in microbial invasion of the blood-brain barrier may be different from those involved in the release of inflammatory mediators and cytokines in response to meningitis-causing pathogens.[8]

Clinical Features

In three fourths of children ultimately diagnosed with ABM, the clinical presentation is subacute, evolving during 2 to 5 days. At onset, affected children typically exhibit a variety of symptoms and signs, such as fever, malaise, decreased interest in surroundings, irritability, alteration in sleeping pattern, anorexia, nausea, vomiting, or diarrhea. These findings are nonspecific, seen with equal frequency in children who are suffering from trivial and self-limited illnesses.[8,9] If the patient is examined early in the course, physical signs may be subtle or lacking.

Children with this insidious presentation have a better prognosis than that of patients with ABM who present with a rapid progression of signs and symptoms. In one fourth of children with ABM, an acute illness with manifestations such as vomiting, fever, and lethargy develops in less than 24 hours. In such patients, the diagnosis is rarely missed.[10] Those with fulminant illness exhibit a higher risk for death as well as immediate and long-term complications.

The cutaneous expression of ABM may be a helpful finding suggestive of specific organisms. Petechial and purpuric eruptions may suggest meningococcemia but also can be seen in cases of pneumococcal disease and *H. influenzae* meningitis. Herpes simplex virus (HSV) infection in the neonate is suggested by blisters or erosions in or around the eye or mouth or on the skin.

Neonatal Period (Up to the Age of 1 Month)

The clinical findings with ABM in the neonate are nonspecific and may include altered vital signs, behavioral changes, neurologic aberrations, dermatologic lesions, and gastrointestinal manifestations (Table 175-1). In the first 30 days of life, patients who present to an ED with a temperature of 38° C (100.4° F) or higher are found to have serious bacterial illness (SBI) and ABM in 4 to 15% and 1 to 2% of cases, respectively.[11] The absence of fever does not eliminate the possibility of SBI because more than half of neonates with meningitis are afebrile or exhibit hypothermia. Other vital sign changes include tachycardia, bradycardia, tachypnea, and apnea. Apnea with cessation of breathing for longer than 20 seconds may signify either seizure activity or a nonspecific medullary respiratory center dysfunction.

Neonates have a limited behavioral repertoire. Within that range, even subtle changes in behavioral patterns can reflect early meningeal involvement. Restlessness, listlessness, increased or decreased sleeping time, and irritability may be clues. Irritability

Table 175-1 Clinical Findings with Bacterial Meningitis

FEATURE	NEWBORN	INFANT AND CHILD
General	Apnea Tachypnea Hypothermia Hyperthermia Bradycardia	Fever Shaking chills Myalgia Neck ache, backache Tachycardia
Behavioral	Restlessness Paradoxical irritability Lethargy	Malaise Irritability Lethargy
Neurologic	High-pitched cry Nystagmus Vacant stare Seizure Opisthotonos Altered tone Nuchal rigidity Bulging fontanel	Altered mentation Focal neurologic signs Hearing deficit Seizure Gait disturbance Photophobia Nuchal rigidity Kernig's and Brudzinski's signs
Dermatologic	Cyanosis Petechiae Purpura Delayed capillary refill Livedo reticularis	Cyanosis Petechiae Purpura Delayed capillary refill
Gastrointestinal	Altered feeding Diarrhea Vomiting Abdominal distention Jaundice	Anorexia Nausea Vomiting

in a neonate without meningeal invasion generally is alleviated by human contact. Increased irritability with cuddling should suggest the diagnosis of ABM. The neurologic manifestation of ABM in the neonate may be a high-pitched cry, incessant cry, absent cry, or moan. A vacant stare, hypertonicity, trembling chin, or bicycling motion of the extremities suggests a seizure. Focal or generalized tonic-clonic activity, although possible, is less commonly seen. Nuchal rigidity occurs in less than 25% of cases of neonatal ABM. A bulging fontanel and diastasis of the sutures, both hallmarks of an increased ICP, are present in approximately 15% of the cases of neonatal ABM.

Rashes are infrequent manifestations of neonatal meningitis.[12] One clue may be generalized pallor accompanied by indistinctly outlined truncal patches of blue discoloration (livedo reticularis). Difficulty in feeding and unusual stooling patterns are nonspecific gastrointestinal features. Nonprojectile vomiting may appear in the course of meningitis, becoming projectile only after ICP has increased. Increased stool volume, irritability during defecation, abdominal distention, hepatomegaly, and jaundice can develop with meningitis.

One Month to 12 Months

In young infants (younger than 3 months), symptoms of SBI are similar to those in the neonate, but as the infant grows older, the social repertoire and motor capability expand, allowing greater opportunity for assessment on physical examination of alteration in behavior or signs and symptoms of bacterial meningitis. Nuchal rigidity, although not commonly present, is highly predictive of ABM in this age group. The absence of nuchal rigidity does not preclude the possibility of CNS infection; however, other signs often are present, such as poor tone, decreased interactiveness, inconsolability, alteration in gaze and focus, and weak cry.

www.ketabpezeshki.com 66485457-66963820

One Year to 5 Years

The cardinal features in this age group are fever, headache, vomiting, and stiff neck. Obtundation and lethargy also are common findings with meningitis but are nonspecific. After the first year of life, neck stiffness with difficulty in flexing the neck is reliably seen during the acute phase of meningitis. A patient rarely may exhibit torticollis.[13] The clinician can attempt to elicit nuchal rigidity by forced flexion of the neck with the child in the supine position. However, this method is less reliable than attempting neck flexion with the child seated with both legs outstretched. Both of these maneuvers involve passive motion that many children voluntarily resist. More reliable methods that have fewer false-negative and false-positive results involve active neck motion on the part of the child. In a toddler, a distracting object can be used to attract eye contact, and the active range of neck motion can be determined. In addition, the neck stiffness that accompanies ABM may be displayed in both the prone and supine positions when the child's shoulders are placed at the edge of the examining table and minimal support of the occiput or forehead is provided manually. Presence of Kernig's sign (flexion of the hip 90 degrees with subsequent pain on extension of the leg) and Brudzinski's sign (involuntary flexion of the hips and knees after passive flexion of the neck performed with the patient supine) is less reliable. Kernig's and Brudzinski's signs are seen in approximately 27% and 51%, respectively, of children 1 to 5 years of age with ABM.[14]

Older than 5 Years

Headache, fever, stiff neck, and alteration of sensorium are common presenting signs and symptoms in children older than 5 years, as they are in the adult patient with ABM.

Diagnostic Strategies

Lumbar Puncture

Indications

Lumbar puncture is indicated in any child in whom bacterial meningitis is suspected (Box 175-1). Patients to be considered candidates for this procedure are those with classic signs and symptoms, such as fever, stiff neck, and photophobia, but in infants and children, classic signs often are absent. In a study by Walsh-Kelly and colleagues, nuchal rigidity was present in only 27% of infants younger than 6 months with bacterial meningitis. By 12 months of age, 71% showed nuchal rigidity; this rate rose to more than 95% by 19 months of age.[15] Therefore, the decision to perform a lumbar puncture in children with suspected meningitis should be based primarily on the constellation of presenting signs and symptoms.

Nuchal Signs. A lumbar puncture should be performed in ill children who exhibit nuchal rigidity or Kernig's sign or Brudzinski's sign and who have suspected meningitis. These three signs of meningeal irritation can also be seen in non-ABM, such as subarachnoid hemorrhage and trauma.

Suspected Sepsis in Young Infants. A bacterial infection is the most likely etiologic disorder in any infant younger than 3 months who is ill.[11] Current practice advocates that the possibility of severe bacterial infection be pursued with an ill young infant. No distinguishing features differentiate sepsis from meningitis in this age group. Because 50% of neonates with acute meningitis are bacteremic at the time of the initial evaluation, and because an intracranial infection subsequently develops in 25% of bacteremic neonates, blood cultures and lumbar puncture should be undertaken concomitantly.[16,17] In infants older than 1 month but younger than 3 months, history and physical examination, even if augmented with selective laboratory investigations (excluding lumbar puncture), may fail to identify those infants with SBI. A lumbar puncture should be undertaken unless there is a contraindication as part of the sepsis evaluation in this age group.[8,18,19]

Toxic Appearance. A lumbar puncture also should be considered in any child with toxic appearance. Such observations include a blunted response to social overtures, poor perfusion, altered motor tone, and abnormal cry. Febrile pediatric patients of all ages with a toxic appearance have an increased incidence of severe bacterial infections, including ABM.[8]

When obvious clues to the source of an apparent infectious process exist and an initial lumbar puncture yields normal findings in the face of increasing severity of illness, additional information can be obtained by repeating the lumbar puncture. The CSF composition may change from normal cellularity to marked pleocytosis within as little as 30 minutes.[20] Thus later reexamination of the CSF may be invaluable in establishing the nature of an occult intracranial infection.

Febrile Illness after Intimate Contact. All children who have prolonged and close physical involvement with persons found to have a serious bacteremic illness require prompt medical evaluation. In particular, a strong indication for lumbar puncture is the development of fever after intimate contact with high-risk patients with meningococcal disease (higher risk: household contacts, children younger than 2 years, history of direct exposure to secretions from index case or having slept in same dwelling 7 days before onset of illness, and passengers seated next to an index case on a flight longer than 8 hours) or *Haemophilus* disease (higher risk: household with at least one contact younger than 4 years who is either unimmunized or poorly immunized, a child younger than 12 months who has not received the primary series of immunizations, an immunocompromised child of any age regardless of *H. influenzae* type b immunization status, and a child who attends daycare where two or more cases have been seen in a 60-day period). Even in the absence of pleocytosis, the emergency physician should consider admission and antibiotic treatment when a child has been exposed to meningococcemia and is symptomatic (e.g., fever, headache) as absence of meningitis is a poor prognosis in this disease.

Febrile Seizures. Children 6 months to 5 years of age who have experienced a simple febrile seizure and who appear well (alert, active, playful) are extremely unlikely to have meningitis. In general, patients who exhibit complex features of the febrile seizure are at increased risk for meningitis. Lumbar puncture should be *considered* in patients who have characteristics that increase their risk for ABM or who show signs and symptoms of ABM. The historical features are age between 6 and 12 months; exposure to another child with meningitis or serious bacterial infection; deficiency in *H. influenzae* or *S. pneumoniae* immunizations, or immunization status cannot be determined; and pretreatment with antibiotics. Children with febrile seizures who exhibit any clinical sign associated with increased risk for intracranial infection, including lethargy, decreased motor tone, doll's eye sign,

Box 175-1 Indications for Lumbar Puncture in Suspected Acute Bacterial Meningitis

- Signs and symptoms of meningitis or toxic appearance
- Suspected neonatal sepsis
- Febrile infant younger than 2 months
- Suspected sepsis in an abnormal host
- *Consider* lumbar puncture in suspected acute bacterial meningitis
  - Febrile illness after intimate contact with person with meningitis or serious bacterial infection
  - Fever and seizure
  - Fever and petechiae

www.ketabpezeshki.com 66485457-66963820

inability to fix and follow, decreased response to painful stimuli, nuchal rigidity, full fontanel, petechiae, and poor skin perfusion, should undergo lumbar puncture.[21]

Fever and Petechiae. Trivial to life-threatening infectious disease can cause fever and petechiae. No current optimal strategy has emerged for evaluation of febrile children with petechial eruptions. Well-appearing febrile children with localized petechiae, especially above the nipple line and with no purpura, are unlikely to have invasive bacterial disease. Patients at highest risk for invasive bacterial disease are more likely to appear ill or to have generalized petechiae and purpura or signs of meningeal irritation.[22] In the high-risk group, unless it is contraindicated by coagulopathy, lumbar puncture should be performed to exclude concurrent meningitis.[23]

Sepsis Suspected in an Abnormal Host. Immunocompromised pediatric patients are at risk for the development of both opportunistic infections and invasive illness from pathogens common to all children. Immunologically incompetent children may not exhibit the typical manifestations of intracranial infections, including nuchal rigidity. However, meningitis should be suspected in an immune-impaired child who experiences only a change in mental status. CSF parameters in these patients are less sensitive indicators of the presence of bacterial meningitis compared with normal host response to a bacterial invasion of the meninges. A lumbar puncture nonetheless should be performed in the process of excluding meningitis in a compromised host.

Penetration of Dura. Fracture through the paranasal sinuses or anterior or middle cranial fossa and penetrating nasal injury or instrumentation may lead to dural tears. Such defects constitute a potential portal of entry for microorganisms into the CNS. Evidence of CNS infection generally is seen within 2 weeks of the initial injury, but clinical manifestations may be delayed for years. Persistent CSF otorrhea or rhinorrhea may be encountered but is not a clinical prerequisite for post-traumatic meningitis. When patients with a recent or remote history significant for craniofacial trauma develop any constellation of symptoms suggestive of meningitis, lumbar puncture should be performed after a computed tomography (CT) scan.

Acute Hearing Loss. Hearing loss has been identified in up to one third of patients with ABM. Hearing impairment may be identified in the acute phase or become apparent only in the post-meningitic period. Of significance, hearing loss may precede the onset of systemic complaints and herald the appearance of meningitis. This is especially true for patients with an inner ear fistula or basilar skull fracture. Acute hearing loss should be an indication for lumbar puncture in patients with traumatic injury, which may have directly inoculated organisms into the labyrinth or basilar subarachnoid space, and in patients who have symptoms suggestive of meningitis.

Contraindications

Most children with ABM exhibit some mental status changes, but rapid onset and progression to deep coma (Glasgow Coma Scale score of less than 8) usually reflect increased ICP, and lumbar puncture is contraindicated.[24] Herniation of the temporal lobes through the tentorium or herniation of the cerebellar tonsils through the foramen magnum rarely occurs in patients with meningitis and increased ICP. Focal neurologic signs suggestive of an abscess are further contraindications to lumbar puncture in children.

Positioning and Precautions

When it is not contraindicated, emergency lumbar puncture with CSF examination should be performed to confirm a presumptive diagnosis of ABM. Patients with suspected bacterial meningitis traditionally were placed in the lateral decubitus position with the spine flexed and the knees drawn upward toward the chest, with shoulders and back perpendicular to the table. Studies with ultrasonography have called this positioning into question and reveal that the interspinous space is greatest in the sitting position with the hips flexed, and neck flexion did not result in increase in the interspinous space.[25] These data reveal that forward head flexion may not be necessary. Opening pressure should be obtained if possible with the patient in the lateral decubitus position. In circumstances in which opening pressure measurement cannot be obtained, an alternative position is sitting with the thighs flexed toward the abdomen.

In the stable monitored patient, the potential for complications is sufficiently low that sampling of the CSF should be routine. Prevention of post–lumbar puncture cephalgia is enhanced by use of smaller gauge needles, restriction of the sample fluid volume to 3 mL, and reinsertion of the stylet before removal of the needle. The small risk of introducing bacterial skin flora is reduced with proper aseptic technique. Causing meningitis by performance of a lumbar puncture in the course of a bacteremic illness is a theoretic concern but does not occur. The information obtained from the lumbar puncture outweighs this hypothetical risk.

Standard Cerebrospinal Fluid Interpretation

A standard CSF examination includes bacterial culture and Gram's stain from tube 1, protein and glucose assessment from tube 2, and blood cell count from tube 3. If there is not an adequate amount of CSF collected, the most important is the specimen sent for culture and Gram's stain. In cases of culture-proven bacterial meningitis, up to 6% of patients have normal glucose and protein levels, few white blood cells, and negative result on Gram's staining. Patients who have received antibiotics before their first lumbar puncture merit special mention. Although the CSF can be sterilized after the administration of antibiotics in the ED, especially in cases of pneumococcal and meningococcal disease, the CSF profile often is unaffected for more than 12 to 24 hours after therapy.[6]

Glucose. The CSF glucose concentration should be interpreted in relation to a concomitant serum glucose value. The normal steady-state ratio of CSF glucose to serum glucose is approximately 0.6. Hypoglycorrhachia, defined as a ratio below 0.4, is characteristically found in cases of ABM with common pathogens and with *Mycobacterium tuberculosis*. Hypoglycorrhachia also may be associated with viral meningitis, although CSF glucose concentration in such cases typically is normal.

Protein. The normal CSF protein range is 55 to 80 mg/dL in newborns (65-150 mg/dL in preterm babies) and 5 to 40 mg/dL in children. Normal to modest elevations in protein concentration occur in the course of viral meningitis. Higher levels of protein are encountered with ABM. After a traumatic lumbar puncture, each 800 to 1000 red blood cells elevate the protein level by 1 mg/dL.

Cellularity. A representative cellularity profile is presented in Table 175-2. Unfortunately, these numbers have been largely derived from healthy or nonsystemically ill children.[26] The standard "panic values" that have been quoted often are more than 2 SDs above the mean or are figures that are seen in only 5 to 10% of studied populations. Cellularity that exceeds these typical threshold values can be seen with conditions that indirectly influence the CNS; however, such cases should be considered to represent possible ABM and treated accordingly. These conditions include generalized seizure, shigellosis, and parameningeal foci of infections such as otitis media, sinusitis, and mastoiditis. Patients with suspected sepsis or with foci of infection distant from the CNS, such as pneumonia, also may have increased cellularity. Classically in ABM, the total CSF white blood cell count ranges from 1000 to 20,000/mm^3. A white blood cell count higher than 2000/mm^3 is present in more than one third of cases of ABM. Significant

www.ketabpezeshki.com 66485457-66963820

Table 175-2 Reported Values for Cerebrospinal Fluid Cellularity

AGE	TOTAL WHITE BLOOD CELLS/µL Mean	Range	Threshold Exceeded
Preterm	7	0-44	>9
Term newborn	8	0-32	>22
0-4 weeks	11	0-50	>35
4-8 weeks	7	0-50	>10
>8 weeks	2	0-8	>6

pleocytosis also can accompany aseptic meningitis in as many as 95% of cases.[27]

Of note, the practice of "correcting" for white blood cells in bloody CSF samples may have little scientific support. Underestimation of the white blood cell count may occur in the setting of culture-positive meningitis. Furthermore, consideration should be given to other illnesses, such as HSV encephalitis, in which an increased number of red blood cells may be seen in the CSF.[5]

In the first month of life, up to 60% of the cells in the normal CSF are polymorphonuclear leukocytes (i.e., neutrophils [PMNs]). Beyond 1 month in the normal state, not more than 3 PMNs/mm^3 should be seen. Shortly after invasion of the meninges, white blood cells can be sampled from the lumbar space. Traditional teaching suggests that a rise in PMNs is characteristic of ABM. However, PMNs and bands may be present in patients with viral meningitis as well.

Gram's Stain. The probability of visualizing bacteria with Gram's staining depends on the number of bacterial organisms present at the time of sampling.[8] One fourth of the smears yield positive results with 10^3 or more colony-forming units (CFUs) per milliliter; 60% of the smears show positive results with 10^3 to 10^5 CFUs/mL, and 97% show positive results with 10^6 CFUs/mL. A positive result on Gram's staining necessitates immediate antibiotic therapy, even in the absence of increased white blood cells and protein levels or decreased glucose level in the CSF.

Other Cerebrospinal Fluid Tests

Antigen Detection. Commercial antigen detection kits are available for the common pathogens causing ABM. Microbial antigens in CSF are detected by coagglutination, latex agglutination, countercurrent immunoelectrophoresis, enzyme-linked immunosorbent assay, and centrifugation-augmented solid-phase immunoassay. Because antigens remain measurable after antibiotic treatment, antigen detection proves to be most effective in cases of partially treated meningitis or in patients in whom the CSF Gram's stain and culture results are negative and ABM is strongly suspected. In any meningitic state, either untreated or pretreated, the CSF antigen detection kits (commercially available to detect multiple organisms in one packaged product) are most sensitive when more than 500 white blood cells are present in the CSF. The antigens typically are present at high levels in the CSF for several days, even after parenteral antibiotics have been initiated. A positive CSF assay result provides reliable bacteriologic diagnosis. A negative antigen test result cannot exclude the diagnosis of ABM.

Cytokines. Assayed concentrations of C-reactive protein, various interleukins, tumor necrosis factor, and prostaglandins are elevated with ABM. These assays require sophisticated techniques and expensive equipment and take several hours to complete. For these reasons, the assays are of little utility in the ED setting.

Polymerase Chain Reaction Testing. Polymerase chain reaction (PCR) is useful in the identification of pathogens in those patients previously treated with antibiotics or in resource-poor settings. It has been shown to have a higher detection rate compared with other tests.[8]

Other Laboratory Testing Instruments

The performance of other diagnostic tests in addition to CSF analysis should be guided by the clinical situation. Blood cultures are of proven value in the patient with ABM. A pretreatment blood culture will identify the organism recovered from the CSF in 86 to 92% of cases. Culture of specimens from body surfaces and orifices (e.g., nose and throat) is not helpful in identifying the causative pathogen. Positive results on culture from urine, stool, and pleural space samples substantiate systemic bacterial disease but do not ensure the presence of an intracranial infection with the same organism.

Determination of serum electrolyte levels and serum glucose concentration may be helpful because changes in body water content and electrolytes may be a feature of ABM. The serum sodium level may be below 135 mEq/L in more than half of the patients at the time of presentation. The blood glucose level should be estimated rapidly with a glucose oxidase tape because hypoglycemia secondary to poor intake, vomiting, and metabolic derangements is a common complication. The estimated value should be confirmed with a serum sample submitted for electrolyte determinations.

No hematologic profiles can consistently identify pediatric patients with ABM; nevertheless, a complete blood count is (CBC) warranted because the total white blood cell count and platelet counts may aid prognostic risk assessment. Either thrombocytopenia or neutropenia at admission may be an ominous feature.

At the time of establishment of the diagnosis of ABM in a moderately ill patient, arterial blood gas determination can be performed in selected cases as indicated by apparent hypoventilation or hypoxia or presence of signs of metabolic acidosis.

Gram's stain smear of a petechial or purpuric lesion may reveal an offending organism causing systemic invasion. Serum C-reactive protein assay, erythrocyte sedimentation rate determination, and measurements of the various cytokines can be used to support the diagnosis of systemic bacterial infection. These tests yield nonspecific findings, however, and cannot be used to include or to exclude a diagnosis of ABM. Elevated pretreatment values may be tracked to determine the most effective duration of therapy for ABM.

A urine specimen should be submitted for analysis. If the patient is pretreated with antibiotic agents, urine microbial antigen detection should be performed. Urine antigen detection may be positive in up to 87% of pretreated cases of ABM. A midstream clean-catch voided specimen or urine acquired by catheterization should be submitted. Urine from a bag specimen that is potentially contaminated by fecal material may yield false-positive results from cross-reactivity with *E. coli* organisms.

Radiology

CT of the head should be performed when the clinical findings suggest subdural empyema, cavernous sinus thrombosis, lateral sinus thrombosis, cerebral hemorrhage, brain tumor, brain abscess, or parameningeal focus of infection. CT of the head without contrast enhancement should be performed on an emergency basis when the patient exhibits signs and symptoms of elevated ICP. Concern for raised ICP is warranted if the patient has cranial nerve palsy, absence of retinal venous pulsations, altered pupillary responses, papilledema, focal seizure, hemiparesis, ataxia, obtundation, persistent vomiting, decorticate or decerebrate posturing, or bradycardia unassociated with hypoxemia. A decision to image the head or other body parts (such as the chest) must not delay

antibiotic administration for patients with ABM. If patients with a ventriculoperitoneal shunt demonstrate fever or signs of increased ICP, they also should undergo CT before tapping of the shunt for CSF.

Differential Considerations

Any of the manifestations of ABM can be expressed in a single patient. The most common presentation involves a combination of thermal instability, altered behavior, blunted mental status, and neck stiffness. The differential diagnosis for this constellation comprises infectious, metabolic, traumatic, and miscellaneous conditions (Box 175-2).

Many conditions cause a child to appear ill. Any infectious agent can cause clinical illness in children, particularly in the first months of life. Infants with infectious disease exhibit altered affect, including significant changes in mental status, strongly suggesting an intracranial pathologic process. Beyond infancy, children may exhibit a toxic appearance with any focal infection or with extensions from a primary focus leading to systemic invasion.[10] In addition to infection, a change in mental status may be noted with endocrinopathy, hypoglycemia, electrolyte imbalance, metabolic disease, uremia, seizure, unintentional trauma, abusive head injury, intussusception, or exposure to toxins.

Nuchal rigidity provokes strong consideration of ABM. However, neck stiffness associated with altered mentation or neurologic deficit can occur with spontaneous intracranial hemorrhage, hemorrhage into brain tumor, epidural abscess, or brain abscess. Other causes of stiff neck include retropharyngeal abscess, peritonsillar abscess, and torticollis.

Viral Meningitis

In the first few years of life, the signs and symptoms of bacterial and viral meningitis can be indistinguishable.[28] Beyond 1 year of age, a majority of children with viral meningitis have a relatively mild illness compared with children with ABM. Fever and retroorbital or frontal headache are frequent symptoms of both diseases. Gastrointestinal disturbances, such as anorexia, nausea, and diarrhea, are more common with viral meningitis. Generalized myalgia also may be a feature, and patients often complain of neck ache or neck stiffness. However, reduction in active neck flexion is uncommon.

Modest elevation of PMNs in CSF specimens coupled with normal glucose level, normal to slightly elevated protein concentration, and negative result on Gram's staining is anticipated with viral meningitis. These laboratory findings can confirm a clinical suspicion of viral meningitis. However, atypical features, such as hypoglycorrhachia and significant pleocytosis, can be found in 20% of encounters. This blurs the distinction between the two states and may alter management. Decision rules have been proposed to distinguish viral from bacterial meningitis, but their usefulness in clinical practice may be limited if they cannot identify every case of ABM. Nigrovic and colleagues, however, demonstrated a low risk (0.1%) for bacterial meningitis in children who lack the following criteria: positive result of CSF Gram's stain, CSF absolute neutrophil count of at least 1000 cells/μL, CSF protein concentration of at least 80 mg/dL, peripheral blood absolute neutrophil count of at least 10,000 cells/μL, and history of seizure before or at the time of presentation.[27]

Management

Management priorities for ABM include airway protection, oxygenation, and volume resuscitation with monitored preservation of organ function. If the capillary refill time is delayed more than 2 seconds or the patient is hypotensive, the patient should be treated for shock. A bolus infusion of 20 mL/kg of normal saline or lactated Ringer's solution should be provided while an indwelling urinary catheter is inserted. Up to 40 mL/kg should be provided as bolus infusions. If vital signs fail to stabilize after an infusion of 40 mL/kg of crystalloid solution and a urine flow of 0.5 mL/kg per hour or more cannot be maintained, vasopressors should be given. In the patient without shock, an hourly infusion rate should be established that provides normal maintenance fluids. Fluid restriction, previously advocated, may be deleterious to the patient's survival and neurologic recovery.

Beyond support of cardiopulmonary and hemodynamic status, initial management of ABM includes prevention of hypoglycemia, control of seizures, and administration of agents to maintain cerebral blood flow.

Antibiotic Therapy

Intuitively, it makes biologic sense to advocate expeditious antibiotic administration for the patient thought to have ABM. In reality, no studies have shown that a duration of any given time frame arbitrarily chosen to constitute an "excessive delay" affects morbidity or mortality; however, most experts agree that antibiotics should be administered within 1 to 2 hours of presentation in patients with suspected ABM. The timing of antibiotic administration in a patient with a CNS syndrome compatible with ABM should be driven by the specifics of the clinical scenario. A conservative approach for children with suspected ABM consists of treatment with empirical antibiotics and hospitalization for observation. Other strategies include stratification of patients into low- and high-risk categories as a basis for appropriate management (i.e., to restrict hospitalization and antibiotic therapy to children with suspected bacterial meningitis).

A major consideration in the choice of antibiotics is the emergence of antimicrobial-resistant organisms, including *S. pneumoniae* resistant to second- and third-generation cephalosporins and gram-negative bacilli resistant to many β-lactam drugs. Thus empirical treatment in areas where there are resistant strains of *S. pneumoniae* needs to include vancomycin.[8] The four clinical categories of patients and their management are as follows.

Nontoxic, low risk: In a non-pretreated patient with no evidence of systemic toxicity in whom the clinical picture is suggestive of viral meningitis, if the CSF indices confirm a clinical suspicion of viral meningitis (negative result on Gram's stain, few white blood cells in the CSF, and normal CSF protein and glucose levels), antibiotics can be withheld in consultation with the patient's primary care physician or a neurologist. Another rarely considered option is to discharge the patient

www.ketabpezeshki.com 66485457-66963820

and to schedule repeated lumbar puncture within 12 hours after antibiotic therapy. These strategies are not without risk because it often is difficult to distinguish viral meningitis from other infections, such as Rocky Mountain spotted fever and ABM. If biochemical parameters or cytologic assessment findings resemble those in ABM, it is appropriate to begin empirical antibiotic therapy and to hospitalize the patient for observation.

Nontoxic, high risk: A patient with no evidence of toxicity but with high-risk historical factors (such as pretreatment with antibiotics, exposure to an invasive organism [*H. influenzae* or *N. meningitidis*], or age younger than 1 year) prompting increased concern for ABM requires blood culture and lumbar puncture for CSF analysis. If the spinal fluid is cloudy, antibiotic therapy should begin immediately rather than being withheld pending complete CSF analysis. In symptomatic patients exposed to a person with meningococcemia, appropriate management consists of a full range of cultures, empirical antibiotic therapy, and hospitalization for observation until the results of all cultures are known because the absence of meningitis does not rule out the presence of meningococcal disease.

Critical, stable: For the patient with classic signs of ABM who has a protected airway, adequate ventilation, normal perfusion, and no evidence of coagulopathy and is assessed as being in critical but stable condition, a blood culture with phlebotomy and a second culture with placement of an intravenous catheter, urinalysis and culture, blood chemistries, and CBC are recommended, after which a lumbar puncture is performed. Antibiotics should be administered immediately after lumbar puncture and before the results of the CSF or other studies become available from the laboratory.

Critical, unstable: A patient with a CNS syndrome, abnormal vital signs for age, unprotected airway, ongoing seizure activity, focal neurologic deficit, or coagulopathy is considered to be in critical and unstable condition. In these patients, the clear risk of an adverse outcome (i.e., respiratory failure) as a result of diagnostic lumbar puncture is magnified, especially if the procedure is carried out before the patient is stabilized. Although the cause and effect relationship is controversial, patients with clinical signs of increased ICP may experience fatal cerebral herniation (even if CT findings are normal) after a lumbar puncture.[24] Two blood culture samples and blood and urine specimens for antigen detection should be obtained. Antibiotics should be administered and the lumbar puncture deferred.

ED antimicrobial treatment decisions are empirically based. The choice of agents should be based on knowledge of the prevalent organisms responsible for intracranial infections and the regional patterns of their antimicrobial susceptibility. The initial regimen chosen for treatment should be broad enough to provide coverage for the various pathogens typical for the age group being treated (Table 175-3).[8]

In the newborn, no single antibiotic has bactericidal activity against all of the possible organisms commonly encountered. The most widely used combination therapy consists of ampicillin with an aminoglycoside or ampicillin plus cefotaxime, which is equally effective. For infants older than 1 month and younger than 3 months, in the absence of any evidence for presence of unusual organisms, conventional therapy is ampicillin and a third-generation cephalosporin. Beyond the age of 3 months, monotherapy with a third-generation cephalosporin provides adequate coverage, except in cases involving resistant strains of *S. pneumoniae*. When gram-positive cocci are identified on the CSF Gram's stain, the combination of a broad-spectrum cephalosporin (e.g., cefotaxime, ceftriaxone) and vancomycin is now routinely recommended.[8]

Steroid Therapy

The role of dexamethasone therapy for ABM has long been the focus of clinical interest. Consensus opinion suggests that for infants beyond 8 weeks of age, dexamethasone may mitigate some neurologic sequelae.[1]

Use of dexamethasone is not without risk. The most commonly reported deleterious effect of dexamethasone is gastrointestinal bleeding. The anti-inflammatory effects of dexamethasone have led to a false sense of clinical improvement, overshadowing the failure of the chosen antibiotic to eradicate an invasive organism. Reduced penetration of vancomycin with dexamethasone therapy has been demonstrated.[29] As a potentially universal distribution of cephalosporin-resistant and penicillin-resistant *S. pneumoniae* approaches, reducing the penetrating effect of vancomycin may cause undue harm. In summary, it is best to adhere to the latest recommendations of the American Academy of Pediatrics (AAP) and to limit the use of dexamethasone to the presumptive treatment of pneumococcal meningitis in infants who are older than 6 weeks after consideration of potential benefits and risks. The AAP recommendation is that dexamethasone may also be beneficial for infants and children with *H. influenzae* meningitis to decrease the risk of neurologic sequelae, including hearing loss, if it is given before or concurrently with the first dose of an antimicrobial agent.[8,30]

For optimal management, close observation is suggested for the patient with newly diagnosed and treated ABM. Vital signs, systemic perfusion, and level of consciousness can rapidly change. Complications from the disease state, such as shock and seizure, or from interventions, such as anaphylaxis and post–lumbar puncture herniation of cerebral contents, can be addressed only if the patient undergoes continuous monitoring.

Acyclovir

The issue of empirical treatment of a neonate or young infant (younger than 3 months) with acyclovir is controversial because identification of infected infants is challenging. Acyclovir should be administered in an ill or febrile infant with a history of maternal HSV infection, presence of vesicles on the skin, seizure, or focal neurologic signs. Use of acyclovir also should be considered in atypical presentations of sepsis or meningitis.[5] The dose of acyclovir is 20 mg/kg intravenously every 8 hours for 21 days in

www.ketabpezeshki.com 66485457-66963820

full-term immunocompetent infants (<35 weeks postconceptual age: 40 mg/kg/day divided q12hr IV for 14-21 days and ≥35 weeks postconceptual age: 60 mg/kg/day divided q8hr IV for 14-21 days). The dose for immunocompromised infants is 750 to 1500 mg/m^2/24 hours divided every 8 hours for 7 to 14 days. PCR assay for HSV should be performed in these cases. Treatment may be initiated on the basis of the criteria outlined earlier before results of PCR tests.

Disposition

A child newly diagnosed with ABM is best managed by experienced physicians and nurses who are capable of addressing critical care needs. The best resource is a hospital that can provide pediatric intensive care. If transfer of the patient to another hospital is necessitated by the lack of appropriate inpatient pediatric care, the composition, expertise, and equipment of the interfacility transport team are important. Strong consideration should be given to the administration of empirical antibiotics. Accordingly, the relevant logistics are best worked out in advance of the actual patient encounter.

SEIZURES

Perspective

A seizure is defined as a paroxysmal event characterized by a change in behavior of the patient; it is caused by abnormal and excessive activity of a group of cortical neurons. The clinical manifestation of the seizure depends on the location and extent of brain involved. Seizures are classified as either provoked or unprovoked. *Provoked* seizures are caused by a broad array of disturbances, including fever, metabolic disarray, and trauma. *Unprovoked* seizures have no clear immedate precedent. *Epilepsy* is commonly defined as the occurrence of two or more *unprovoked* seizures.

Seizure disorders are the most common neurologic disorders of childhood; 4 to 10% of children suffer at least one seizure in the first 16 years of life. Etiology, clinical appearance, and electroencephalographic patterns differ from children to adults.

Principles of Disease

Pathophysiology

The young (<5 years), immature nervous system is remarkably susceptible to seizures. Early in development, excitatory activity predominates and inhibitory systems are undeveloped.[32] This is known as the period of vulnerability. A paucity of synaptic connections and alterations in the synthesis of neurotransmitters also may play a role.

Seizures and Brain Damage

It is well known that children with epilepsy are at a significant risk for cognitive impairment and behavioral abnormalities. It is difficult to distinguish the relative contributions of the effect of the seizures from the underlying CNS disease and from the effect of anticonvulsants. A single prolonged seizure (>30 minutes) has been shown to damage the brain, particularly the temporal lobes and hippocampus.[33] In addition, a growing body of evidence points to the lasting effect of repetitive, brief seizures in early childhood.[34]

Clinical Features

Classification of Seizure Type

Seizures are classified into two main types: partial (consciousness is maintained) and generalized (consciousness is lost) (Box 175-3). There are two types of partial, or focal, seizures: complex and simple. In *complex partial* seizures, the patient experiences a change in level of awareness and may exhibit bizarre behaviors, including staring, lip smacking, wandering, or picking at clothing. In *simple partial* seizures, the patient experiences no change in mentation.

Unknown
- Epileptic spasms

From Berg AT, et al: Revised terminology and concepts for organization of seizures and epilepsies: Report of the ILAE Commission on Classification and Terminology, 2005-2009. Epilepsia 54:676, 2010.

Generalized seizures may be *convulsive* or *nonconvulsive*. A convulsive seizure may start focally and secondarily generalize. The most common type of generalized nonconvulsive seizure is an absence seizure. Absence seizures are marked by a brief arrest of consciousness and movement typically lasting 5 to 30 seconds; no postictal drowsiness occurs. In children, it may be difficult to differentiate a brief complex partial seizure, in which a child may stare and not respond, from an absence seizure.

Classification of Epilepsy: Epileptic Syndromes

An epileptic syndrome is characterized by a triad of age at onset, seizure type, and electroencephalographic findings. Identification of the epileptic syndrome provides information on prognosis and informs management decisions. Several of the more common epileptic syndromes of infancy and childhood are reviewed (Box 175-4).

Infantile Spasms

Infantile spasms are manifested during the first year of life with rapid flexor or extensor spasms that appear in clusters. The electroencephalogram (EEG) shows *hypsarrhythmia*, an abnormal pattern characterized by high-voltage slow waves and disorganized spike activity.

Approximately two thirds of children with infantile spasms have an underlying CNS disorder, such as a congenital brain malformation or tuberous sclerosis. The outcome is poor; only half will attain remission of seizures, and the large majority will be mentally retarded. Treatment is notoriously difficult. In the United States, a course of ACTH has traditionally been the treatment of choice; prednisolone treatment is being used with increasing frequency.[35] Vigabatrin was recently approved by the U.S. Food and Drug Administration (FDA) for the treatment of infantile spasms and is particularly useful in the setting of tuberous sclerosis.

Modified from Berg AT, et al: Revised terminology and concepts for organization of seizures and epilepsies: Report of the ILAE Commission on Classification and Terminology, 2005-2009. Epilepsia 54:676, 2010.

Childhood and Juvenile Absence Epilepsy

Childhood and juvenile absence epilepsy begins between 4 and 12 years of age and is characterized by frequent absence seizures; generalized convulsive seizures occur in up to 50% of the patients. The diagnosis is frequently missed for prolonged periods; the parent or physician may assume the child is daydreaming or purposely not responding. Bursts of spike-and-wave activity at 3/second on the EEG during an absence spell are indicative of this syndrome. Hyperventilation can trigger absence seiziures and can be used to diagnose absence epilepsy. Treatment is with ethosuximide; if convulsions also occur, valproic acid or lamotrigine are used instead.[36] The prognosis is excellent, and the majority of children outgrow this disorder by 16 years of age.

Benign Epilepsy with Centrotemporal Spikes

This epilepsy syndrome typically begins between 3 and 13 years of age. The seizures occur most commonly during sleep and involve the facial muscles; secondary generalization frequently occurs. The typical electroencephalographic pattern is one of central temporal (rolandic) spikes, particularly during sleep. The prognosis is excellent; the seizures typically cease by 16 years of age. Considerable controversy exists as to whether anticonvulsant treatment of a patient with brief, infrequent seizures is warranted.[37]

Lennox-Gastaut Syndrome

Developmental disability, multiple seizure types and a "slow" spike and wave pattern on EEG in a young child (2-5 years) are the characteristics of Lennox Gastaut Syndrome. Infantile spasms commonly evolves into Lennnox Gastaut. Valproic acid, lamotrigine, topiramate, felbamate, and rufinamide have shown promise for the treatment of Lennox-Gastaut syndrome,[38] but treatment is notoriously difficult.

Febrile Seizures

A febrile seizure is defined as a seizure occurring in the presence of fever without CNS infection or other cause. A *simple* febrile seizure is generalized, lasts less than 15 minutes, and occurs in a neurologically and developmentally normal child between 6 months and 6 years of age.[39] Simple febrile seizures typically occur early in the course of the febrile illness. Temperature does not need to be markedly elevated; almost half the children with a febrile seizure have a documented temperature below 39° C. *Complex* febrile seizures are diagnosed when multiple seizures occur during the same illness, the seizures are prolonged (longer than 15 minutes), or the seizures have a focal component.

Febrile seizures are common, occurring in 2 to 5% of children. Thirty percent of children with a simple febrile seizure will have a recurrence; of these, half will have a third event.[40] The younger the age at onset, the higher the likelihood of recurrence. Children with simple febrile seizures have a 2 to 3% chance for development of epilepsy (compared with a 1% rate of epilepsy in the general population). Those with complex febrile seizures have a significantly higher risk. Treatment with long-term anticonvulsants does not affect the later risk of epilepsy.[41]

Rectal diazepam (Diastat) is safe and effective for the termination of prolonged or repetitive febrile seizures and should be available for home use in the child with recurrent, prolonged febrile seizures.[42] Long-term anticonvulsant use is rarely warranted.[39] The use of antipyretics, such as acetaminophen and ibuprofen, does not decrease the likelihood of recurrence.[43] Reassurance and education are the mainstays of management (see the section on management of febrile seizure and the discussion about lumbar puncture).

Neonatal Seizures

The frequency of seizures is higher in the first month of life than at any other time in childhood. Neonatal seizures may be subtle; apnea, sustained eye deviation, chewing, or limb bicycling movements may be the only apparent signs. There is a high incidence of subclinical electrographic seizures.[44] Focal clonic movements are often associated with an underlying structural lesion.

Although there are many causes of neonatal seizures, a relatively few account for a majority of cases. These include hypoxic-ischemic encephalopathy, intracranial infection, congenital brain malformation, cerebrovascular events, and metabolic

www.ketabpezeshki.com 66485457-66963820

disturbances, particularly hypoglycemia and hypocalcemia (Box 175-5). Although inborn errors of metabolism are rare, early treatment can be lifesaving.

Neonatal seizures may predispose to the development of cognitive and behavioral difficulties and to an increased risk of epilepsy later in life, although the prognosis ultimately depends on the etiology of the seizure.[44]

Status Epilepticus

Convulsive status epilepticus is a true neurologic emergency; it is associated with high morbidity and mortality rates that increase with duration of the seizure activity. Status epilepticus is defined as greater than 30 minutes of either continuous seizure activity or repeated brief seizures without full recovery of consciousness between seizures. In clinical practice, any seizure lasting more than 5 minutes warrants intervention.[45] Although the diagnosis of convulsive status epilepticus usually is obvious, the duration of the seizures often is underestimated because the intensity of the jerking tends to diminish with time. The importance of careful observation cannot be overstated.

Status epilepticus occurs significantly more frequently in children than in adults, particularly in those younger than 1 year.[46] Febrile illness is by far the most common precipitant of status epilepticus in children. Medication change, toxic ingestion, idiopathic epilepsy, metabolic derangements, and congenital abnormalities are the next most common. Although morbidity and mortality rates are significantly lower than in adults, they are still significant at 30% and 4%, respectively.

Nonconvulsive status epilepticus is marked by an altered mental status. Patients may demonstrate confusion, unresponsiveness, abnormal motor movements, twitches, lip smacking, or automatisms. An EEG can confirm the diagnosis and should be obtained if nonconvulsive status is suspected.

Etiology of Seizures and Differential Considerations

Differential Diagnosis

The first task of the ED evaluation is to determine whether the event in question was truly a seizure. Box 175-6 lists disorders that may be mistaken for seizures.

Syncope is one of the more common disorders mistaken for a seizure. Syncope is characterized by a sudden loss of consciousness and motor tone caused by a transient global cerebral hypoperfusion. Just before the event, the patient will often complain of lightheadedness and blurry vision and may appear pale and sweaty. Postictal confusion does not occur, but trembling and stiffening are common. Vasovagal syncope is common in otherwise healthy children and does not warrant further workup unless it is recurrent. On the other hand, cardiogenic syncope, such as prolonged QTc syndrome, is potentially fatal. Syncope should be considered if there is no post ictal period or tonic or clonic activity, if the event occurred during exercise or if palpitations were present.

Breath-holding spells occur in 4 to 5% of children, primarily between the ages of 6 and 18 months. They are triggered by pain or emotional upset. The child becomes pale or cyanotic and may lose consciousness. If so, the child is typically limp, but a brief period of clonic movements or opisthotonos may occur. The average attack lasts approximately 40 seconds.[47]

Migraines may mimic seizures, particularly when they are accompanied by an aura, motor dysfunction, clouding of consciousness, or vomiting.

Disorders of sleep are distinguished by excessive daytime sleepiness or by disordered nighttime sleep. In *narcolepsy,* daytime sleep attacks, sleep paralysis, hypnagogic hallucinations (vivid hallucinations while falling asleep), and cataplexy (sudden loss of motor tone) occur. Cataplexy may be mistaken for atonic or absence seizures. *Nocturnal enuresis* may raise concern for an unwitnessed nighttime seizure associated with incontinence. In *night terrors* (pavor nocturnus), the child wakens suddenly, crying, inconsolable, and unresponsive; the event concludes with the child's returning to sleep. *Sleepwalking (somnambulism)* and *sleeptalking (somniloquy)* are common among school-age children.

Movement disorders may mimic seizures. *Tics* are rapid, repetitive, brief involuntary movements that occur intermittently and in flurries. Those most commonly seen are eye blinking and head shaking. Patients do not lose consciousness. *Shudder attacks* are uncommon but easily mistaken for seizures. The movement is that of the chill experienced when cold water runs down the back. *Paroxysmal choreoathetosis* is an abnormal motor movement that may be spontaneous or triggered by the child's movement.

Behavioral or psychiatric disturbances can produce behaviors that may appear epileptic. *Panic attacks* may be mistaken for

complex partial seizures. The patient has a sudden sensation of intense fear accompanied by shortness of breath, dizziness, palpitations, sweating, choking, chest discomfort, and fear of dying. *Psychogenic seizures* are involuntary events that mimic seizures. Many children with psychogenic seizures also have epileptic seizures. Prolonged electroencephalographic monitoring may be necessary to differentiate an epileptic seizure from a psychogenic seizure.

Infants with gastrointestinal reflux may exhibit *Sandifer's syndrome,* characterized by episodes of abnormal posturing, arching of the back, and torticollis.

Etiology of Seizures in Children

After the diagnosis of seizure is made, the seizure type and the etiology should be determined. Seizures can be divided into three main etiologic categories: acute symptomatic, remote symptomatic, and idiopathic seizures (Box 175-7).

Acute symptomatic seizures are provoked by an acute event. Febrile seizures are the most common cause of acute symptomatic seizures in children. Remote symptomatic seizures are due to an earlier, or remote, CNS lesion. Examples include cerebral palsy, congenital brain malformation, and any other chronic brain injury. Idiopathic seizures have no definable cause.

Acute Symptomatic Seizures

Fever is the most common cause of acute symptomatic seizures in children. Meningitis should always be considered in any patient with seizures and fever. The section below on febrile seizures further discusses this important issue. In general, a child whose mental status is normal both before and after the seizure is unlikely to have meningitis.

Inborn errors of metabolism or metabolic disease is a common cause of seizures in children. Hypoglycemia (blood glucose concentration of less than 60 mg/dL in adults and less than 40 mg/dL in children), hyponatremia (serum sodium concentration of less than 125 mEq/L), and hypernatremia (serum sodium concentration of more than 150 mEq/L) are associated with seizures. Dehydration is the most common cause of hypernatremia.

Hypocalcemia and hypomagnesemia may lead to muscle spasms, paresthesias, hyperactive reflexes, weakness, tetany, as well as seizures. Hypocalcemic seizures are a common cause of neonatal seizures.

Post-traumatic seizures occur in as many as 15% of children after head injury. *Impact seizures,* occurring within 1 hour of a head trauma, are not associated with significant injury or with the later development of epilepsy; however, it may be difficult to distinguish these from seizures associated with intracranial injury, and a CT scan of the head without contrast enhancement is indicated. *Early post-traumatic seizures* (occurring within the first week of injury) may arise from cerebral edema or intracranial hemorrhage, laceration, or contusion. Phenytoin is effective in preventing early post-traumatic seizures but does not influence the development of epilepsy.[48]

Brain tumors cause a wide variety of symptoms, depending on their location and the type of tumor. Infratentorial tumors, the most common location in the pediatric population, do not typically cause seizures.

Seizure may be the presenting sign of stroke. Congenital heart disease, sickle cell anemia, and homocystinuria are major risk factors for ischemic stroke in children. Vascular malformations, such as arteriovenous malformations, may cause hemorrhagic stroke.

Numerous drugs are known to cause seizures. Cyclic antidepressants, cocaine and other stimulants, antihistamines, and isoniazid are the most common agents of drug-induced seizures. Drugs that may be associated with seizures are summarized in Box 175-8. Seizures also may occur during drug withdrawal, usually within 48 hours of drug cessation. Drug withdrawal in the neonate is a significant issue. Withdrawal of benzodiazepines and barbiturates leads to an abstinence syndrome similar to ethanol withdrawal.

Reflex seizures are precipitated by a specific, identifiable stimulus. For example, flashing lights on television or video games may induce seizures in photosensitive children.[49]

Remote Symptomatic Seizures

Causes of remote symptomatic seizures include congenital brain malformations, neurocutaneous disorders, cerebral palsy and neurodegenerative disease.

Diagnostic Strategies

The initial diagnostic evaluation is directed toward determination of whether the event was indeed a seizure and, if so, identification of a specific underlying cause. If the patient arrives in the ED actively convulsing, the first priority is to stop the seizure.

Nicotine

A complete history is key to establishment of the diagnosis of a seizure or epilepsy. Effort should be made to obtain a description from an eyewitness as well as an account from the patient. The history should include the following.

Events leading up to the attack: What was the patient doing at the time? Did the patient become confused or complain of dizziness, a bad smell, flashing lights, or anything else?

The event itself: Did the patient get stiff or limp? Did the patient shake? Was there a loss of consciousness? Did the eyes or head turn in one direction? Was there incontinence? Having the observer demonstrate the movements can be helpful.

Events directly after the attack: Was the patient lethargic or confused and for how long? Did the patient remember the event? The occurrence of postictal confusion, headache, or fatigue can help differentiate a seizure from a nonepileptic event.

Possible precipitants of seizures: Has there been recent fever, illness, rash, head trauma, drug use, or medication or supplement use?

Risk factors for epilepsy: Is there a past history of meningitis, head injury, febrile seizures, congenital anomalies, or developmental delay? a family history of epilepsy? presence of unusual color or number of birthmarks?

Previous history of abnormal movements, staring spells, or myoclonus: It is not uncommon for a patient with a first generalized tonic-clonic seizure to have underlying, undiagnosed absence epilepsy.

Box 175-9 Summary Approach to the Child with a Seizure

- Determine if the event was truly a seizure.
- Determine seizure type.
- Identify precipitating factors (e.g., hypoglycemia, hypocalcemia, electrolyte imbalance, low anticonvulsant levels, fever, trauma, central nervous system infection, toxin) and treat accordingly.
- Determine if anticonvulsant therapy is appropriate at this time.

In a patient with known epilepsy who has a breakthrough seizure, determine the dosage of anticonvulsant, whether any doses were missed, whether any new medications or supplements were started, any precipitants (fever, illness, trauma, etc.) present, and the baseline frequency of seizures.

The general physical examination should concentrate on signs of systemic disease that can cause seizure. Particular attention should be paid to evidence of meningitis, trauma, drug use, dehydration, hypertension, and heart disease. Skin lesions, such as café au lait spots or hypopigmented nevi, may point to a neurocutaneous disorder. An abnormal head circumference may point to hydrocephalus or abnormal brain growth.

A careful neurologic examination should assess for signs of increased ICP and focal neurologic deficits.

Management

The management of four categories of seizures—febrile seizures, afebrile seizures, neonatal seizures, and status epilepticus—is described next. Box 175-9 provides an overview of the approach to a child with a seizure.

Febrile Seizures

In general, a child with fever between 6 months and 5 years of age who presents after a brief seizure (<15 minutes) with a normal neurologic examination can be assumed to have had a simple febrile seizure.[39] Blood and urine testing may be required as part of the work up for the fever, but is not required for work up of a febrile seizure. According to the newer AAP recommendations, lumbar puncture is not necessary in children older than 12 to 18 months in whom the clinical findings are not suggestive of meningitis. Lumbar puncture should be considered in children between 6 and 12 months of age whose vaccination status for *H. influenzae* type b or *S. pneumoniae* is incomplete and in children who have been pretreated with antibiotics.[21] Lumbar puncture should be strongly considered in children younger than 6 to 12 months because signs of meningitis can be subtle in this age group. Electroencephalography and neuroimaging generally are not required.

Afebrile Seizures

Laboratory Studies. Laboratory tests generally include determinations of calcium, glucose, urea, electrolytes, and magnesium.[50] The results of such studies are rarely abnormal in the child who is neurologically normal after a brief seizure.[51] If drug exposure is a possibility, toxicology screen is sent. Anticonvulsant levels are measured if applicable.

A lumbar puncture is mandated in the patient with an abnormal mental status or other signs of meningitis, regardless of whether fever is present. If the concern for meningitis is low in a postictal patient, it is acceptable to observe the patient over the next 2 to 3 hours, and if the patient returns to baseline, a lumbar

www.ketabpezeshki.com 66485457-66963820

puncture can be avoided. A prolonged seizure can cause a mild elevation of white blood cells in the CSF, presumably from a transient disruption of the blood-brain barrier. CSF should be sent for cell counts, protein and glucose concentrations, culture, and PCR for HSV.

Radiography and Other Imaging. Consensus is lacking in regard to the need for neuroimaging in children who arrive in the ED after a first seizure. Emergent imaging should be performed in a patient with new focal deficits, persistent altered mental status, recent trauma, persistent headache, or partial-onset seizures.[52] Because a generalized convulsion may have begun as a focal onset seizure, it is crucial to obtain a careful history from both an eyewitness and the patient. Children with generalized unprovoked seizures and normal examination findings do not necessarily require acute imaging. At follow-up evaluation, further evidence, such as a focal abnormality on the EEG, may indicate a need for neuroimaging, which can be done at that time. Children with a history of epilepsy do not need neuroimaging unless there is a change in clinical status.

If imaging is indicated in the acute period, either CT or magnetic resonance imaging (MRI) may be used. Although MRI provides superior anatomic detail, sedation is commonly needed in the pediatric patient, thus masking assessment of the patient's mental status. Therefore, CT, which provides rapid imaging and is highly sensitive for detection of acute blood and fractures, is often the imaging study of choice in the child with a seizure.

Special Procedures. The EEG is the most important laboratory test for evaluation of the patient with an unprovoked seizure. It rarely needs to be performed in the acute situation unless nonconvulsive status epilepticus is suspected. The EEG helps determine the seizure type, specific epilepsy syndrome, and risk for recurrence.[51] Transient postictal slowing may occur for several days after a seizure.

Sleep deprivation, hyperventilation, and photic stimulation are techniques that can enhance the sensitivity of the EEG. Ideally, all EEGs should be recorded while the patient is awake, drowsy, and asleep.

Treatment of Specific Causes of Acute Seizures. Hypoglycemia in children older than 2 months is treated with an intravenous bolus of 10% dextrose, 2.5 mL/kg. Neonates are treated with 2 mL/kg of 10% dextrose solution. Severe symptomatic hyponatremia may be treated with the intravenous administration of 3% saline (2 mL/kg infused during 30 minutes) to raise the serum sodium level by 3 to 7 mEq/L. The remainder of the correction should occur slowly during the next 24 hours. Hypernatremia is corrected slowly during 48 hours. Hypocalcemia is treated with 10% calcium gluconate, 100 mg/kg intravenously; the patient should be on a cardiac monitor during the infusion. Toxic ingestions are treated based on the specific toxin involved. One specific example is the treatment of isoniazid poisoning with pyridoxine. The dose of pyridoxine is 1 g IV for every gram of INH ingested. When the quantity of INH ingested is unknown, 5 g IV may be administered to an adult and 70 mg/kg (maximum 5 g) to a child.

Empirical treatment with antibiotics is ordered if meningitis is a possibility. (see Table 175-3). The patient with altered mental status and focal seizures is treated additionally for herpes encephalitis with acyclovir, 20 mg/kg per dose (10 mg/kg per dose in children older than 12 years) every 8 hours. In patients with acute significant brain injury, such as depressed skull fracture or intracerebral hematoma, anticonvulsant treatment reduces the incidence of early seizure, and should be given. Although there is no consensus on the ideal drug, phenytoin is most commonly used as it does not cause significant sedation and is conveniently loaded intravenously. The optimal duration of therapy is not clear and depends in part upon the severity of injury.

Neuroimaging
Head ultrasound examination
Head computed tomography
Brain magnetic resonance imaging

Neonatal Seizures

The common underlying causes of neonatal seizures differ from those in older children and adults (see Box 175-5). The diagnostic assessment of neonatal seizures is detailed in Box 175-10. It includes metabolic testing, CSF analysis, and neuroimaging. Glucose, calcium, magnesium, and electrolyte levels and CBC are determined immediately. If findings are normal, lactic acid, ammonia, and pH determinations should be considered. As clinical assessment for meningitis is not reliable in young infants, lumbar puncture is performed and fluid sent for cells, protein and glucose determinations, culture, and herpes PCR assay. Head CT or MRI should be obtained. In the unstable neonate, a head ultrasound scan may be performed at the bedside to rule out a neurosurgical emergency, until more definitive imaging can be obtained.

Empirical antibiotic therapy should be started in affected infants (see previous section on meningitis). Acyclovir (20 mg/kg per dose every 8 hours) is initiated if herpes encephalitis is a clinical concern (red cells in CSF, continued seizures with no other clear etiology). Hypoglycemia is corrected with 2 mL/kg of 10% dextrose solution intravenously.

Hypocalcemia is treated with either 10% calcium gluconate (1 mL/kg over 5 to 10 minutes with monitoring of the heart rate and infusion site) or calcium chloride (0.2 mL/kg). Hypomagnesemia, which may be associated with hypocalcemia, is treated with a 0.25 mL/kg dose of 50% solution magnesium sulfate injected intramuscularly.

Phenobarbital is typically the drug of choice for neonatal seizures. A loading dose of 20 mg/kg is given; additional doses of 5 to 10 mg/kg may be given if necessary. If seizures continue, fosphenytoin 20 PE/kg may be loaded. Lorazepam 0.1 mg/kg intravenously may be useful but is associated with hypotension and respiratory depression. Refractory seizures may be treated with midazolam infusion.[34] Continuous electroencephalographic recording is necessary at this point. If seizures are refractory to medical treatment, empirical treatment with pyridoxine, 100 mg

www.ketabpezeshki.com 66485457-66963820

Management

Impending/Established Status

Out-of-hospital or No IV Access Available
Buccal midazolam (0.2 mg/kg), intranasal midazolam (0.2 mg/kg) or rectal diazepam (0.3 mg/kg).

Emergency Room
Lorazepam 0.1 mg/kg IV (max 5 mg) over 1 min
Allow 5 minutes to determine whether seizure terminates.

Give oxygen. Stabilize airway, respiration, and hemodynamics. Obtain IV access. Check bedside glucose. Begin ECG monitoring. Avoid hyperthermia, hypoglycemia, and hyperglycemia.

If hypoglycemic, administer bolus of 2 ml/kg 50% glucose. Consider thiamine 100 mg IV first.

Repeat benzodiazepine administration if patient has not received 2 doses of benzodiazepines. (Be sure to consider pre-hospital dosing).

Administer 2nd anticonvulsant:
Fosphenytoin 25-30 mg PE/kg IV at 3 mg PE/kg/min (max 150 mg PE/min) (PE = phenytoin equivalents)
Phenytoin 25-30 mg/kg IV at 1 mg/kg/min (max 50 mg/min)

If < 2 years, consider pyridoxine 100 mg IV push.

Testing to be considered:
Bedside Glucose, Basic Metabolic Panel, Magnesium, Phosphate, Complete Blood Count, Liver Function Panel, Coagulation Tests, Anticonvulsant Levels, Toxicology, Cultures, Head CT.

Draw phenytoin level (~10 min after infusion completed)

Refractory Status

If seizure continues 10 minutes after fosphenytoin/phenytoin infusion then patient has refractory SE regardless of time elapsed.

Administer 3rd anticonvulsant:
Levetiracetam 40 mg/kg IV at 5 mg/kg/min.
Consider in patients with hemodynamic instability or possible metabolic/liver disease. OR
Valproate Sodium 40 mg/kg at 5 mg/kg/min.
Contraindicated if liver disease, thrombocytopenia, or possible metabolic disease. OR
Phenobarbital 30 mg/kg IV at 2 mg/kg/min (max rate 60 mg/min).
May cause respiratory depression and hypotension.

If seizure continues 5 minutes after 3rd anticonvulsant, then consider administration of different third-line anticonvulsant, or proceed directly to pharmacologic coma initiation.

Admit to PICU. Prepare to secure airway, mechanically ventilate, obtain central venous access and continuous hemodynamic monitoring through arterial line.

Once clinical seizure terminates may need EEG monitoring to assess for non-convulsive seizures.

Initiate coma with midazolam 0.2 mg/kg bolus (max 10 mg) over 2 min and then initiate infusion at 0.1 mg/kg/hr. If clinical seizures persist 5 min after initial midazolam bolus then administer additional midazolam bolus of 0.2 mg/kg bolus. Continue infusion. If clinical seizures persist after another 5 minutes, then administer another midazolam bolus of 0.2 mg/kg and increase infusion to 0.2 mg/kg/hr. Repeat as needed.

If seizure persist at maximum midazolam (generally 2-3 mg/kg/hr) or midazolam infusion is not tolerated, then consider transition to pentobarbital (3-5 mg/kg bolus followed by maintenance infusion of 0.3-3 mg/kg/hr, up to 10 mg/kg/hr).

Other options include: Isoflurane or Propofol.

Consider addition of topiramate, valproic acid, levetiracetam, or ketamine.

Malignant Status

Continue pharmacologic coma for 24 hours after last seizure with EEG goal of burst-suppression.

Continue initial medications and check levels:

Ensure an additional anticonvulsant is administered to provide coverage during weaning coma.

Reduce midazolam by 0.05 mg/kg/hr every 3 hours with frequent EEG review. If no clinical or electrographic seizures then wean until off.

Continue EEG for at least 24 hours after end of infusion to evaluate for recurrent electrographic seizures.

If clinical or subclinical seizures occur then re-institute coma with midazolam for 24 hours. Start midazolam at infusion rate that achieved burst suppression (approximately 50/50) and increase according to suggested midazolam titration algorithm.

Add additional anticonvulsants (topiramate, levetiracetam, ketamine, high dose phenobarbital).

Additional imaging (3 Tesla MRI, consider Magnetoencephalography) and surgical evaluation.

Airway, Breathing, Hemodynamics, Temperature, Glucose Levels

EEG Monitoring

Figure 175-1. Management of status epilepticus in children. *CT,* computed tomography; *ECG,* electrocardiography; *EEG,* electroencephalography; *MRI,* magnetic resonance imaging; *PICU,* pediatric intensive care unit; *SE,* status epilepticus. (Modified from Abend NS, Gutierrez-Colina AM, Dlugos DJ: Medical treatment of pediatric status epilepticus. Semin Pediatr Neurol 17:169, 2010. Used with permission.)

www.ketabpezeshki.com 66485457-66963820

intravenously, is indicated. This will abort seizures in the rare child with pyridoxine dependency syndrome.

Status Epilepticus

Status epilepticus is a true medical emergency. Position the patient to maximize ventilation and to prevent aspiration. The cervical spine must be protected if trauma cannot be ruled out. Oxygen is administered by nasal cannula or face mask. A large suction catheter should be available to suction secretions. In the younger patient, the tongue may obstruct the airway; a nasopharyngeal airway will keep the tongue forward and improve respiratory status.

If there is evidence of increased ICP, the airway is compromised, or respiratory failure occurs, the patient should be intubated. Do not paralyze unless absolutely necessary because this will mask signs of seizure activity. Short-acting neuromuscular blockers, such as succinylcholine and vecuronium, should be used if needed.

Monitor heart rate, blood pressure, respiratory rate, and pulse oximetry and treat hyperthermia with antipyretics and cooling blankets. Place an intravenous line and send blood samples for electrolyte values, glucose concentration (including rapid blood glucose test), calcium and magnesium levels, renal function tests, liver function tests, antiepileptic levels (if indicated), and CBC. Urine should be sent for toxicology.[53]

Correct any metabolic abnormalities (see previous section on afebrile seizures). If necessary, an intraosseous line may be used.

Begin anticonvulsant treatment as quickly as possible. Figure 175-1 presents a protocol for treatment of status epilepticus in a child.[54] Benzodiazepines, particularly lorazepam and diazepam, are the initial drugs used in the treatment of status epilepticus. They diffuse quickly into the CNS, rapidly terminating seizure activity 70% of the time. The recommended pediatric intravenous dosage for lorazepam is 0.1 mg/kg (maximum 4 mg) over 1 minute. Hypotension, respiratory depression, and impaired consciousness may occur.

Rectal diazepam may be used if intravenous access cannot be obtained. The dosage is 0.5 mg/kg (maximum 20 mg). If Diastat, a rectal preparation of diazepam, is not available, the intravenous preparation may be instilled through a lubricated feeding tube inserted 4 to 6 cm into the rectum. Buccal and intranasal midazolam preparations at a dosage of 0.2 mg/kg are also effective.[55]

If the seizure continues, give a second dose of benzodiazepine. If the seizure continues, load fosphenytoin (use phenytoin, if fosphenytoin is not available); patients who already are receiving phenytoin should receive phenobarbital 20 mg/kg instead.

Fosphenytoin is a water-soluble phosphate ester of phenytoin that is rapidly converted in plasma to phenytoin. Unlike phenytoin, fosphenytoin can be administered intramuscularly, can be administered with common intravenous solutions, and is substantially less cardiotoxic and less sclerosing to the vasculature. In addition, it can be given three times more rapidly than phenytoin. Fosphenytoin produces plasma concentrations similar to those achieved for phenytoin in the same time.

The standard loading dosage of fosphenytoin is 20 PE (phenytoin equivalents)/kg at 3 PE/kg per minute (maximum of 150 PE/min). The loading dose of phenytoin is 20 mg/kg at a rate of 1 mg/kg per minute (maximum of 50 mg/min). Monitor cardiovascular status, including blood pressure and electrocardiogram, with either medication. If hypotension results, decrease the rate of infusion.

If the seizure continues, a third drug is loaded. The most commonly used drug is phenobarbital, at a loading dose of 20 mg/kg at a rate of 2 mg/kg per minute (maximum dose of 60 mg/min).

Because phenobarbital can cause apnea, depressed consciousness, and hypotension, all of which are more pronounced in the presence of benzodiazepines. Other options for the third medication have begun to take precedence. These include valproate sodium and levetiracetam. Valproate sodium is loaded at a dose of 40 mg/kg at 5 mg/kg/min. It is contraindicated in the presence of liver disease, thrombocytopenia, or possible metabolic disease. Levetiracetam is loaded at 40 mg/kg at 5 mg/kg/min.

If the seizure continues, either a different third-line medication is used or, pharmacologic coma is induced. Concurrent electroencephalographic monitoring is helpful at this point. If the patient has not yet been intubated, do so now.

Midazolam is a safe and effective benzodiazepine used to treat status epilepticus that is refractory to conventional agents. A bolus of 0.2 mg/kg over 2 minutes is followed by infusion of 0.1 mg/kg per hour.[56] The dose is increased every 15 minutes as necessary to a maximum of 3 mg/kg per hour. Tachyphylaxis may occur, necessitating high doses.

If midazolam is not well tolerated or seizures persist, pentobarbital may be administered with an initial bolus of 5 mg/kg IV followed by a continuous infusion of 0.5 to 5.0 mg/kg per hour. Severe hypotension, cardiovascular toxicity, and postinfusion weakness are common complications of pentobarbital coma.

Propofol also has been shown to be highly effective in the treatment of refractory status. An initial intravenous bolus of 1 to 2 mg/kg is followed by infusion of 2 to 10 mg/kg per hour.[57] Propofol is contraindicated in children on the ketogenic diet.

Nonconvulsive status epilepticus is more difficult to recognize and often requires electroencephalography for diagnosis. Treatment is with benzodiazepines or intravenous valproic acid.[58]

Once the seizure has been effectively terminated, neuroimaging and lumbar puncture are indicated.

Disposition

Hospitalization is unnecessary for most patients after a first brief unprovoked seizure as long as the neurologic examination is normal and follow-up evaluation is possible. Electroencephalography and imaging studies can be performed on an outpatient basis.

Children with simple febrile seizures can almost always be sent home. Warden and Hauser and their colleagues outlined advice to be given to families in the ED[59,60] (Box 175-11).

For the child who had a prolonged febrile seizure or cluster of seizures, a prescription for rectal diazepam (Diastat AcuDial, 0.5 mg/kg per rectum rounded up to the nearest 2.5 mg; maximum of 10 mg in young children and 20 mg in older children) can be prescribed for outpatient use after consultation with the child's neurologist or primary care physician. Instruct parents to give Diastat *only* if a seizure continues beyond 5 minutes and to then call emergency medical services for transportation to the ED for further evaluation.

Children who have had a prolonged seizure or who are not back to their baseline within a few hours should be admitted to the hospital. Hospitalization is also recommended if adequate follow-up evaluation cannot be arranged or in the case of extreme parental anxiety.

Initiating Anticonvulsant Therapy

The decision to start anticonvulsant prophylaxis must balance the risk for recurrence of seizure against the potential complications associated with long-term medication use.

Side effects of medication are common and include sedation, dizziness, blurred vision, ataxia, gastrointestinal disturbances, and cognitive and behavioral changes. Idiosyncratic reactions include hepatotoxicity, agranulocytosis, aplastic anemia, rash, Stevens-Johnson syndrome, and serum sickness.

Two thirds of children with a first unprovoked seizure never experience a recurrence.[60] The risk for recurrence is increased with

www.ketabpezeshki.com 66485457-66963820

Box 175-11 Advice to Parents about Simple Febrile Seizures

- Febrile seizures occur in 2 to 5% of all children between the ages of 6 months and 5 years.
- These seizures may appear frightening to observers but generally are harmless.
- Simple febrile seizures often occur in the first 24 hours of the febrile illness and occur only once. If the seizure recurs, your child should be reevaluated.
- A febrile seizure may be manifested by body stiffening, twitching of the face or arms and legs, eye rolling, jerking of the arms and legs, staring, or loss of consciousness.
- Febrile seizures generally last less than a minute but can last up to 15 minutes.
- Your child may appear not to be breathing and the skin color may become darker; if so, call 911 or emergency personnel and lay the child on the floor on his or her back. Do *not* place your fingers in the child's mouth.
- Febrile seizures do not cause brain damage or paralysis.
- A child who has febrile seizures has only a slightly increased risk for development of a seizure disorder compared with a child who never had a febrile seizure.
- Febrile seizures tend to run in families.
- Febrile seizures can recur with subsequent febrile illnesses. Medicines generally are not given to prevent simple febrile seizures.
- Use of medicines such as acetaminophen or ibuprofen for fevers has not been shown to prevent febrile seizures.

Modified from Warden CR, et al: Evaluation and management of febrile seizures in the out-of-hospital and emergency department settings. Ann Emerg Med 41:2, 2003.

the presence of neuroimaging or electroencephalographic abnormalities, developmental delay, family history of epilepsy, remote symptomatic seizure, occurrence of the first seizure during sleep, or Todd's paralysis. If none of these risk factors is present, the 5-year recurrence risk is only 21%.

There is no evidence that early treatment with anticonvulsant medications after a single seizure alters the later risk of epilepsy,[61] nor is there evidence to show that a single self-limited seizure causes neurologic sequelae.

Balancing this information, anticonvulsants generally are started only after a second unprovoked seizure and, if possible, only after consultation with the patient's primary care provider or a neurologist.

Patients with acute symptomatic seizures associated with a risk factor for recurrence, such as cerebral hemorrhage, meningitis, or contusion, should be treated in house with prophylactic anticonvulsants, such as phenytoin or fosphenytoin. When the patient is stable, the decision to continue or to discontinue treatment is made.

The choice of medication is dictated by the seizure type and syndrome and the side effect profile of the agent. Drug levels must be monitored with the older anticonvulsants, but most of the newer anticonvulsants do not necessitate monitoring.

Of the older medications, phenytoin, phenobarbital, valproic acid, and carbamazepine are all excellent medications for treatment of generalized and partial seizures. However, phenytoin is a poor long-term choice in children because of the development over time of hirsutism, gum hyperplasia, and facial coarsening. Phenobarbital is rarely used in children older than 2 years because of the high rate of hyperactivity, sleep disturbances, and lowered intelligence quotient (IQ). Because of its consistent absorption and excellent safety profile, phenobarbital is frequently used in infants. Of the older medications, carbamazepine is the first choice for the management of partial epilepsy. It should be noted that carbamazepine, as well as phenytoin, can worsen absence and myoclonic seizures. Valproic acid is a first-line treatment for primary generalized epilepsy and is particularly useful for myoclonic and absence seizures. Because valproic acid has a relatively high incidence of hepatotoxicity, particularly in children younger than 2 years, as well as significant teratogenicity, newer anticonvulsants are often used first. Ethosuximide is the drug of choice for absence seizures; it is not effective for convulsive seizures.

In the past 20 years, several new anticonvulsants have been approved by the FDA. These include gabapentin, felbamate, lamotrigine, topiramate, zonisamide, oxcarbazepine, levetiracetam, vigabatrin, lacosamide, rufinamide, and clobazam. Their role in the management of pediatric epilepsy is becoming increasingly important. Table 175-4 provides a summary of the commonly used anticonvulsants in children.

HEADACHES IN CHILDREN

Perspective

Headache is an extremely common problem in children and adolescents. Even though a majority of patients have benign causes of headaches, which usually can be diagnosed by a careful history and physical examination, neuroimaging with CT or MRI or both may be necessary in selected cases. Proper diagnosis, treatment, and close monitoring of these patients are extremely important to ensure that no serious cause of the headache has been overlooked.

Studies of schoolchildren have indicated that 40% of children will experience a headache by 7 years and 75% will experience a headache by 15 years of age and that migraine (one of the most common causes of headache in childhood) occurs in 1% of children by 7 years and 5% of children by 15 years of age. Studies in the United States have found that the highest incidence (246 episodes per 100,000 person-years) of migraine headache is in boys 10 to 14 years of age.

Principles of Disease

Several pathophysiologic theories have emerged to explain the mechanisms of headache. However, there is still ongoing debate as to whether the vascular component of migraines or neurogenic inflammation is the sole basis for the clinical expression of headache. The *vascular theory* proposes that headaches are produced by dilation of intracranial or extracranial arteries. The change in vessel diameter triggers the auras before and the pain during a headache; the dilation may be relieved by vasoconstrictive drugs, such as ergots. The *neuronal theory* proposes that headaches are due to a primary dysfunction of the brain; a wave of spreading neuronal depression is accompanied by decreased cerebral blood flow. Serotonin (5-hydroxytryptamine [5-HT]) may be a key mediator in this cascade of events. Serotonin agonists have been shown to relieve migraine pain. The *trigeminovascular theory* is an integrated hypothesis that combines elements of both theories. The trigeminal nerve makes synaptic connections with cerebral blood vessels, and the headache is an expression of the nerve–blood vessel interaction. Another theory that combines elements of the vascular and neuronal theories suggests that an initial electrical phenomenon beginning in the cerebrum initiates a cascade of events that affects the vasculature, with the release of biochemical substances leading to neurogenic inflammation.[63,64]

Clinical Features

Headaches can be classified into five temporal patterns: acute, acute recurrent, chronic progressive, chronic nonprogressive, and mixed. An *acute* headache is new in onset and different from previous headaches; it can herald a broad range of conditions

*Not including sedation and dizziness.

ranging from a viral illness to a subarachnoid hemorrhage. *Acute recurrent* headaches can be expressed as periodic events separated by pain-free intervals. *Chronic progressive* headaches occur during weeks to months. They can signify serious medical disorders, such as brain tumors or arteriovenous malformations. *Chronic nonprogressive* headaches usually occur for years and are classified as primary headaches (as opposed to secondary symptomatic headaches). *Mixed* headaches are acute recurrent headaches (migraine) superimposed on a pattern of daily chronic nonprogressive headaches.[63,65]

The primary goal of the ED evaluation is to differentiate symptomatic headaches from primary headaches, such as migraine or tension headaches. The history is critical in investigating children's complaints of headache and is the most important component of the evaluation to determine the correct diagnosis. Both the patient and family members should be asked about specific factors related to the headache. Rothner has created a patient questionnaire to generate a "headache database" from which clinicians can formulate a diagnosis, which is presented in Box 175-12.[65]

In addition to the important questions in Box 175-12, the clinician must focus on a detailed history of the neurologic system to identify any related symptoms (e.g., lethargy, ataxia, seizures, weakness, visual disturbances) and a general review of other organ systems. Warning signs of symptomatic headaches include recent onset, occurrence with straining or athletic endeavors, association with neurologic symptoms, change in headache pattern, nocturnal awakening, and bilateral occipital headaches. Additional information related to the past medical history (e.g., history of recent head

Box 175-12 Patient Questionnaire to Generate Headache Database

- Do you have more than one type of headache?
- How did the headache begin?
- Was there associated trauma or infection?
- How long has the headache been present?
- Are the symptoms worsening or staying the same?
- How often do the symptoms occur and how often do they last?
- Do the headaches occur at any special time or circumstance?
- Are the headaches preceded by warning signs?
- Where does it hurt?
- What is the quality of the pain? Is there pounding or a sharp sensation?
- Do you have any associated symptoms during the headache? abdominal pain? Is there any nausea or vomiting?
- Do you stop what you are doing during the headache?
- Do you have any other medical problems?
- Are you taking other medications?
- Are there activities that make the headache worse?
- Does any medication make the headache better?
- Does anyone in your family have headaches?
- What do you think is causing your headache?

Data from Lewis DW, Rothner DA: Headache in children and adolescents. In Johnson RT, Griffin JW, McArthur JC (eds): Current Therapy in Neurological Diseases, 6th ed. Philadelphia, Mosby, 2002.

www.ketabpezeshki.com 66485457-66963820

trauma, neurologic or psychiatric disorders, hospital admissions, medications) also is important to obtain.

The physical examination, including vital signs, should be performed in a careful manner with particular attention to those findings unique to children. Height, weight, and head circumference should be compared with standard percentiles and the child's previous growth history; a change in the rate or direction of growth may indicate an intracerebral mass or hydrocephalus. Blood pressure also should be carefully measured, with use of age-appropriate cuff size and percentiles for age. The child's head also should be auscultated for bruits associated with arteriovenous malformations, and a skin examination should be performed to look for stigmata of neurocutaneous disorders, such as neurofibromatosis. The neurologic examination should begin with assessment of the child's mental status, language, and level of consciousness. It also should include assessment of cranial nerves; gait analysis; cerebellar, sensory, and motor function testing; and evaluation of deep tendon reflexes. The ophthalmologic examination should include pupillary reactivity, visual acuity, extraocular movements, and funduscopy. Observation of interactions between the patient and family members also may provide clues to potential family problems, depression, or anxiety.

Differential Considerations and Headache Syndromes

The list of differential considerations for headache is extensive (Box 175-13).[66]

Acute Headache

The acute headache is a common problem in children and adolescents and accompanies many infectious processes. In the absence of other signs of CNS involvement (such as nuchal rigidity or alteration in level of consciousness), headaches in febrile children usually do not constitute evidence of CNS infection. In fact, nonspecific viral illnesses represent a majority of diagnoses in children presenting to the ED with an acute headache.

The most common cause of subarachnoid hemorrhage in young adults is a ruptured cerebral aneurysm. In younger children, rupture of an arteriovenous malformation that is near the subarachnoid space may cause subarachnoid and intraparenchymal hemorrhage. A common site of bleeding is the anterior cerebral artery with resulting pressure on the third cranial nerve. Varying degrees of ptosis, lateral deviation of the eye, and pupillary dilation may be seen with this type of aneurysm.

Box 175-13 Differential Diagnosis of Headache

Aneurysm, arteriovenous malformation
Congenital malformation (e.g., Dandy-Walker syndrome)
Hydrocephalus
Hematoma: subdural, epidural (acute), intraparenchymal
Hypertension
Infectious: viral illness, abscess, meningitis, encephalitis
Metabolic
Neoplasm
Pseudotumor cerebri
Subarachnoid hemorrhage; berry aneurysm rupture
Toxic (medication, cocaine abuse, analgesia rebound)
Trauma

Data from May A, Goadsby PJ: The trigeminovascular system in humans: Pathophysiologic implications for primary headache syndromes of the neural influences on the cerebral circulation. J Cerebr Blood Flow Metab 19:115, 1999.

If subarachnoid hemorrhage is suspected, CT of the head (non–contrast enhanced) should be performed as soon as possible. If the CT scan does not show subarachnoid blood, a lumbar puncture should be performed because head CT findings are normal 5 to 10% of the time, especially if only a small amount of bleeding has occurred. The first and last samples taken in the lumbar puncture are examined for cells to eliminate the possibility of a "traumatic tap" (in which the number of red blood cells would be expected to decrease by the last tube) and the presence or absence of xanthochromia.

Localized acute headaches commonly are due to sinusitis, otitis media, dental disorders, or traumatic head injury. Dental disorders usually are accompanied by pain localized to the teeth, gums, or jaw. Temporomandibular joint dysfunction usually is associated with unilateral pain in the ear, jaw, or mouth. Headache associated with trauma must always be carefully investigated for the possibility of subdural or epidural hematomas, fractures, and leptomeningeal cyst (a "growing" skull fracture in a child 3 years of age or younger with a history of recent trauma). Ophthalmologic problems, such as astigmatism, refractory errors, eye strain, and squint, also are occasionally responsible for headaches in children.

Chronic Progressive Headache

The chronic progressive headache category is composed of disorders that cause progressively severe headaches in children. The development of increased ICP, which can be caused by brain tumors, pseudotumor cerebri, hydrocephalus, brain abscess, or intracranial bleeding, is a major problem in this category. Headache that awakens the child or is present on first awakening is a classic symptom of increased ICP. Impaired venous outflow in the supine position leads to excess fluid (blood, CSF, or edema) inside the skull, leading to increased pressure. Nocturnal or morning emesis also may suggest increased ICP. The physical examination may show symptoms or signs of increased ICP (papilledema, brisk reflexes, cranial nerve deficits, upturning toes in response to stimulation of the sole of the foot, decreased level of consciousness) as well as focal symptoms related to the location of the lesion (e.g., hemiparesis, ataxia, visual field deficits).

Headaches may be the first symptom of a brain tumor and as such occur with increasing frequency with age. In a study by Flores and colleagues, 18% of 0- to 5-year-olds, 52% of 6- to 10-year-olds, and 68% of 11- to 20-year-olds who had brain tumors presented with headaches. Only 38% of primary brain tumors were diagnosed within the first month after the onset of symptoms. More than 50% of these patients had at least three associated symptoms or signs, such as nausea, vomiting, visual effects, problems with walking, weakness, changes in personality or school performance, or speech changes. The most common neurologic findings were papilledema, abnormal eye movements, ataxia, abnormal tendon reflexes, and abnormalities on the visual examination.[67]

Clinical findings with pseudotumor cerebri (idiopathic intracranial hypertension) are secondary to the increased ICP and include papilledema, sixth cranial nerve palsy, and visual field obstruction. This condition is more common in females and in younger children is associated with obesity; presence of otitis media or head trauma; use of vitamin A, steroids, birth control pills, or tetracycline; presence of menstrual irregularities or diseases that produce obstruction of the CSF pathways; and obstruction of the major venous sinuses. By definition, neuroimaging findings are normal. The lumbar puncture usually demonstrates elevated pressure, often higher than 20 cm H_2O, and normal CSF protein and glucose levels. Neuroimaging should precede lumbar puncture when increased ICP is suspected from mass or injury. Treatment can include diuretics and repeated lumbar puncture for

www.ketabpezeshki.com 66485457-66963820

removal of CSF.[68] Hydrocephalus may be related to a previous episode of meningitis, subarachnoid hemorrhage, or head injury or may be congenital.

Brain abscess can result from meningitis, head trauma, chronic otitis media and sinusitis, or septic embolization in children with congenital heart disease. Focal neurologic signs as well as fever and headache also may be present, but the patient may look surprisingly well. CT of the head without contrast enhancement is not sufficiently sensitive when an abscess is considered in the differential; CT with and without contrast enhancement or MRI is indicated. CSF findings (performed only after neuroimaging) usually include a mild leukocytosis (10-200 leukocytes/mm^3), slightly elevated protein level, and normal glucose level. The CSF smear and culture usually do not reveal any organisms.

A subdural hematoma is associated with head trauma. Symptoms include those associated with increased ICP; seizures and other focal neurologic deficits also may be present. The diagnosis is confirmed by neuroimaging. Postconcussive headaches are common. These headaches can be severe and associated with dizziness and vomiting. Chronic progressive headache also can be a symptom of systemic diseases, such as hypertension, collagen vascular disease, hypothyroidism, Lyme disease, mononucleosis, or inborn errors of metabolism.

Migraine Headache

The diagnosis of migraine is based on symptoms of recurrent headaches separated by pain-free intervals. A revised classification of migraine syndromes has been produced for pediatric migraine (Box 175-14).[69]

Migraine headaches are classified primarily into migraine with and without an aura. *Migraine without an aura,* also known as *common migraine,* is the most frequent type of pediatric and adolescent migraine and includes the following criteria: more than five attacks that last 1 to 48 hours (untreated), accompanied by either nausea and/or vomiting or photophobia and/or phonophobia, and including a minimum of two of the following criteria: unilateral location, pulsing quality, moderate to severe intensity, and aggravated by routine physical activities.

Migraine with an aura, previously known as *classic migraine,* is diagnosed when at least two attacks fulfilling the diagnosis of migraine occur accompanied by a variety of sensory warning symptoms, such as flickering lights, loss of vision, and tingling or numbness. The symptoms develop during 5 minutes or more and completely resolve within 60 minutes.[69,70]

Hemiplegic migraine is characterized by the sudden onset of hemiparesis or loss along with headache in the contralateral hemisphere. This type of migraine is seen more frequently in children than in adults. Even though symptoms usually last for hours or days, affected persons rarely are left with permanent deficits. *Ophthalmoplegic migraine* is characterized by severe unilateral eye pain and headache, followed by ipsilateral third nerve palsy of variable degree. Rarely, the fourth or sixth cranial nerve, rather than the third nerve, may be affected. *Basilar artery migraine,* also common in children, is manifested with a combination of visual symptoms (e.g., transient bilateral blindness, blurred vision) and visual hallucinations, vertigo, ataxia, loss of consciousness, and drop attacks. An *acute confusional state* consists of a change in personality, orientation, or behavior. The *Alice in Wonderland syndrome* includes perceptions of distortion in body images and shapes. Objects appear either much larger (macropsia) or smaller (micropsia) before, during, or after a headache.

Migraine variants are not uncommon and can be misdiagnosed. *Abdominal migraine* is characterized by recurrent abdominal pain, nausea, vomiting, and recurrent headaches. Benign paroxysmal vertigo is manifested as the sudden onset of vertigo, pallor, and nystagmus. *Paroxysmal torticollis* is defined as recurrent episodes of head tilt associated with headache, nausea, and vomiting. Of note, this is a diagnosis of exclusion. A child with a head tilt, vomiting, and headache should first be evaluated for a posterior fossa lesion. *Ocular migraine* is characterized by transient monocular visual blurring to blindness with bright flashes of light.

Epilepsy and migraine headache are distinct clinical syndromes, yet they share several characteristics, such as aura, vertigo, nausea, pallor, loss of consciousness, drowsy postictal state, confusion, and transient focal neurologic deficits. The incidence of seizures is higher in patients with migraine than in the general population. The differentiation of these two clinical entities may be difficult in certain cases. Headache as the sole manifestation of a seizure is uncommon; however, headaches frequently may follow tonic, tonic-clonic, and brief complex partial seizures. Bilateral frontal throbbing headaches also may follow episodes of status epilepticus. Further neurologic evaluation, including electroencephalography, may occasionally be necessary to try to distinguish between these two syndromes.

Box 175-14 1998 Revised Criteria for Pediatric Migraine without an Aura

A. Five or more attacks fulfilling features B through D.
B. Headache attack lasting 1-48 hours (*adults:* 2-72 hours)
C. Headache has at least two of the following features:
   1. Either bilateral or unilateral (frontal-temporal) location (*adults*: unilateral)
   2. Pulsating quality
   3. Moderate to severe intensity
   4. Aggravated by routine physical activities
D. At least one of the following accompanies headache:
   1. Nausea and/or vomiting
   2. Photophobia and/or phonophobia (*adults:* both photophobia and phonophobia)

Chronic Nonprogressive Headache

Chronic nonprogressive headache commonly is seen in the adolescent population. Included in this category of headache are muscle contraction headache, depressive equivalents, and conversion headaches. The International Headache Society classification of headaches refers to these types of headaches as *tension headaches*. This type of headache includes the following symptoms: bilateral or unilateral; nonthrobbing, pressing, or bandlike tightness of mild to moderate intensity; and the absence of nausea, vomiting, and aura. These headaches are further classified as either episodic (10 to fewer than 15 episodes/month lasting 30 minutes to 7 days) or chronic (more than 15 episodes/month for more than 6 months).

Cluster Headache

Cluster headache is a distinctive headache syndrome more commonly seen in male patients. The syndrome rarely is seen in those younger than 10 years. Cluster headache is characterized by one to several attacks recurring each 24 hours, during several weeks to months, with headache-free periods between the cluster headaches. The headache-free periods may last months to years. The pain is throbbing, severe, and unilateral; occurs over the same orbitotemporal region; and is associated with ipsilateral scleral injection, lacrimation, nasal stuffiness, and, less often, partial Horner's syndrome (enophthalmos, ptosis, miosis, and anhidrosis, unilateral affecting sympathetic innervation of the eye). The pain

www.ketabpezeshki.com 66485457-66963820

lasts 30 minutes to several hours and can occur at any time of day or night.

Diagnostic Strategies

The diagnosis of a specific headache syndrome usually is determined by the history and physical examination. The primary goal of the ED evaluation is to eliminate the possibility of an intracranial lesion or serious extracranial pathologic condition. Skull radiography and electroencephalography are of limited value in this setting for the routine evaluation of children with chronic headaches.

Radiology

CT of the head and cranial MRI are both excellent studies to evaluate patients with headaches but are often not needed emergently.[71] In general, MRI provides superior anatomic detail compared with a CT scan. MRI is particularly useful in the detection of abnormalities in the sella turcica, posterior fossa, and cervicomedullary junction. MRI also is better at detection of arteriovenous malformations and low-grade tumors. However, a patient cannot be closely monitored during the MRI study, and MRI is not always available in the ED. CT scan is superior to MRI in the detection of acute blood and skull fractures. Therefore, CT is usually the modality of choice in the ED if neuroimaging is required. However, most patients presenting with headache do not require neuroimaging. Indications for the use of neuroimaging are presented in Box 175-15.[68]

Laboratory and Special Procedures

Lumbar puncture occasionally is helpful in the evaluation of patients with headache. If the possibility of a mass lesion is a concern (as suggested by history of early-morning headaches and vomiting or focal neurologic findings on physical examination), radiologic imaging should precede the lumbar puncture. The lumbar puncture is a necessary procedure to determine the presence of an infectious process, subarachnoid hemorrhage, or idiopathic intracranial hypertension.

Box 175-15 Indications for Radiologic Imaging in Patients with Headache

Strongly Indicated If
- Abnormal neurologic examination findings
- Signs and symptoms of elevated intracranial pressure
- Meningeal signs plus focal neurologic findings or altered mental status
- Progressive or new neurologic signs
- Significant head trauma
- Severe nocturnal headaches that awaken the patient from sleep or are present on awakening
- Severe (characterized by patient as "worst headache of my life") headaches of increasing frequency and duration
- Presence of ventriculoperitoneal shunt
- Chronic progressive headache

Consider If
- Headache or vomiting on awakening
- Unvarying location of headache, especially occipital
- Persistent headache plus no family history of migraine
- Neurocutaneous syndrome
- Age younger than 3 years (limited verbal skills)

Data from Qureshi F, Lewis D: Managing headache in the pediatric emergency department. Clin Pediatr Emerg Med 4:159, 2003.

In a patient with suspected chronic progressive headaches, the headaches may be a symptom of a systemic disease. Laboratory tests that may be considered include CBC; urinalysis; erythrocyte sedimentation rate determination; antinuclear antibody assay; liver function studies; thyroid function studies; serum lipid assay and determination of serum magnesium, lactate, and pyruvate concentrations; and Lyme disease titer.

Management

Treatment of primary childhood headaches requires attention to initial pharmacologic management as well as reassurance, removal of potential triggering factors, and initiation of a behavioral management program.[64,70,72,73,75,76] Nonmedical interventions may have some impact and should be strongly considered. These include avoidance of triggers, placement of the child in a darkened room with minimal or no extraneous noise, avoidance of hypoglycemia by feeding during a migraine, avoidance of caffeinated beverage (except for possible use as a migraine medication during an acute migraine), application of a cool compress on the forehead, use of a gentle fan, and breathing exercises and relaxation techniques.[64] A headache diary is important to help the patient identify potential triggers and the effects of medications. Common triggers include reduction in sleep, perimenstrual stress, missed meals, and foods (such as chocolate, processed meats, alcohol, hard cheeses, red wine, monosodium glutamate, yeast extracts, nuts, figs, aspartame, and sauerkraut). Children with primary headaches are not hospitalized for care unless the diagnosis is uncertain and a serious cause of secondary headache is being considered.

Migraine

Treatment of migraine headache includes analgesics, vasoconstrictors, sedatives, triptans, antiemetics, anti-inflammatory agents, and other modalities.[64,72,73,75,76] The patient should be placed in a quiet and safe environment. Simple analgesics and rest are the first line of treatment for patients with migraine as well as nonmigraine headache. Medications include acetaminophen (pediatric: oral or rectal, 10-15 mg/kg/dose po/pr q4-6h, maximum dosage 90 mg/kg/24 hours; adolescent: 325-650 mg/dose, maximum dosage, 4 g/24 hours) and the nonsteroidal anti-inflammatory drugs (aspirin, 10-15 mg/kg/dose, 650-1000 mg for patients 12 years of age and older, maximum dosage 4 g/24 hours; ibuprofen 5-10 mg/kg/dose q6-8h; or 400 mg/dose for those 12 years of age and older, maximum daily dose of 1200 mg per day; or naproxen 2.5-5.0 mg/kg/ dose q8-12h, 250-300 mg for those 12 years of age and older to a maximum daily dosage of 1000 mg/24 hours). Some children respond well to small doses of caffeine.

For severe migraine episodes, more potent analgesics may be needed. These include ketorolac tromethamine (Toradol), a nonsteroidal anti-inflammatory that can be used parenterally in children who are vomiting (0.5 mg/kg intravenously or intramuscularly every 6 hours, to a maximum dose of 30 mg); codeine (0.5 to 1.0 mg/kg per dose every 4 to 6 hours orally, to a maximum dose of 60 mg); and oxycodone (0.05 to 0.15 mg/kg orally per dose every 4 to 6 hours, to a maximum dose of 5 mg every 6 hours). Combination medications, such as Fiorinal (butalbital, aspirin, and caffeine), Fioricet (butalbital, acetaminophen, and caffeine), and Midrin (isometheptene, acetaminophen, dichloralphenazone) also are effective. The dose is 1 or 2 capsules in children older than 12 years. Caution should be used in prescribing these medications. In addition to producing an analgesic effect, these medications may produce alterations of emotional state, sedation, and psychological dependence.

Vasoconstrictor drugs are used less commonly in the adolescent population than in the adult population. Antiemetic agents,

www.ketabpezeshki.com 66485457-66963820

although not as well studied in the pediatric as in the adult population, also may be considered. This group of dopamine receptor antagonists includes metoclopramide (in children older than 14 years: 10 mg intravenously × 1; children younger than 14 years: 0.1 to 0.2 mg/kg per dose intravenously), promethazine (in children: 0.25 to 0.5 mg/kg per dose intramuscularly or rectally every 4 to 6 hours as needed; in adults: 12.5 to 25 mg every 4 to 6 hours as needed), and prochlorperazine (in children weighing more than 10 kg or older than 2 years: 0.4 mg/kg per 24 hours orally or rectally, divided three to four times per day, or 0.1 to 0.15 mg/kg per dose intramuscularly, three to four times per day). Dystonic reactions with antiemetics are more common in children, so these agents should be used with caution in this population. Brousseau, in one of the few pediatric randomized clinical trials examining the efficacy of prochlorperazine compared with ketorolac for the treatment of acute migraine, found that by 60 minutes, a greater reduction in headache pain was obtained in the prochlorperazine group, even though 30% of patients in each group experienced some recurrence of headache symptoms.[77] In older patients who may be treated for nausea without sedation, ondansetron (a serotonin receptor antagonist) can be considered (0.15 mg/kg per dose intravenously or 4 to 8 mg/day orally).

Sumatriptan is a selective 5-HT_1 receptor agonist that can mediate cerebral vasoconstriction and block inflammatory response; it can be administered orally, intranasally, or subcutaneously. A review of medication trials of triptans in children with migraine highlighted the important finding that randomized clinical trials found no difference in outcome between the control and the experimental groups.[72] However, nasal sumatriptan (5 to 20 mg, repeated in 2 hours, to a maximum daily dose of 40 mg) has been shown to be effective in the adolescent population, along with oral preparations of 25 to 50 mg (repeated in 2 hours, to a maximum daily dose of 200 mg).[73] Sumatriptan should be avoided in persons with cardiac disorders or hypertension and in patients who have received an ergot alkaloid in the preceding 24 hours. Other newer 5-HT1 agents, such as zolmitriptan (Zomig) at doses of 2.5 mg intranasally and 5 mg orally compare favorably with sumatriptan. In a recent randomized clinical trial, the onset of significant pain relief was seen at 15 minutes asfter treatment with 5 mg of zolmitriptan nasal spray and at 1 hour produced a higher headache response rate compared with placebo (58.1% vs 43.3%).[74] Cluster headaches, which are brief and may not respond to oral therapy, can be treated with inhalation of oxygen at 4 to 5 L/minute, the ergot alkaloid Cafergot, or sumatriptan.[65] The most recently released triptan is a combination of sumatriptan and naproxen sodium (Treximet). It is approved for the treatment of migraine in adults only, although there is a recently completed adolescent clinical trial that could result in its approval.[64]

The use of pharmacologic agents for prophylaxis in children with migraine headache requires careful observation and follow-up evaluation by the child's primary care physician. The indications for use of these medications include more than two or three headaches per week and interference with lifestyle, particularly missed schooldays or inability to participate in social activities. In keeping with or perhaps reflecting the high spontaneous remission rate of childhood migraine, the placebo effect of many medications is high. Controlled studies are extremely limited. Medications that have been used include propranolol (initiated slowly at a dose of 2 to 4 mg/kg per day, divided three times a day; contraindicated in asthma patients), amitriptyline (initiated at a dose of 25 mg at bedtime for adolescents; baseline electrocardiogram is recommended), calcium channel blockers, anticonvulsants (particularly valproic acid), cyproheptadine, and naproxen sodium. Cyproheptadine, valproic acid, and naproxen are available in liquid form, which is a valuable feature in the pediatric population. Methysergide should be avoided in children owing to serious side effects, including retroperitoneal fibrosis. Amitriptyline may be useful for adolescents with a diagnosis of migraine and muscle contraction headaches and in depressed children with headaches.

PEDIATRIC ATAXIA

Perspective

Ataxia comes from the Greek word *ataktos,* meaning "lacking order," and describes a pathologic abnormality of organization or modulation of movement.[78]

Pathophysiology

Ataxia can be caused by congenital abnormalities or can be acquired. Congenital ataxia is associated with CNS abnormalities. Acquired ataxia can be acute, episodic, or chronic. The chronic ataxias are usually caused by inherited metabolic or genetic disorders. Most commonly, ataxia is caused by cerebellar dysfunction. Lesions in the corticospinal tract or dorsal columns of the spinal cord may also be causative.

Clinical Features

Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or sudden development of a wide-based "drunken" gait. The history should identify any recent infection, injury, inadvertent drug ingestion, or other family members with the same problem. Mental status usually is normal in cases of postinfectious ataxia. If it is abnormal, the possibility of ingestion, acute disseminated encephalomyelitis, or stroke should be considered. Nystagmus is common if the cerebellum is affected. Papilledema or cranial nerve palsies suggest hydrocephalus or a central nervous system lesion.[79]

Differential Considerations

In children, 40% of ataxia cases are caused by acute cerebellar ataxia (Box 175-16). Boys are more commonly affected, with the highest incidence at the ages of 2 to 4 years. Seventy percent of patients have a history of recent illness with multiple causative

agents, but varicella virus is the most common, with up to 26% of cases associated with varicella. Coxsackievirus and echovirus are other etiologic agents. The disease is thought to be due to an autoimmune phenomenon leading to cerebellar demyelination. Symptoms and signs are maximal at onset, with the extremities more seriously affected than the trunk, and range from unsteadiness and wide-based gait to complete inability to walk. Mental status is normal, and nystagmus is common. Fever and seizures are uncommon outcomes.[79]

Acute postinfectious demyelinating encephalomyelitis can also cause ataxia and occurs in the recovery phase of a viral illness or vaccination. It is distinguished from acute cerebellar ataxia by alteration in consciousness and multifocal neurologic deficits as well as by fever and the frequent occurrence of seizures. Brainstem encephalitis can involve the cerebellum, causing ataxia in association with focal neurologic abnormalities and respiratory irregularities. Etiologic agents include Epstein-Barr virus, *L. monocytogenes,* and enteroviruses.[78,79]

Up to 32% of cases of acute childhood ataxia are due to drug toxicity, most commonly from ingestion of anticonvulsants, benzodiazepines, alcohol, or antihistamines and less commonly from exposure to organic chemicals or heavy metals. The ataxia usually is accompanied by lethargy, confusion, and inappropriate speech or behavior. Nystagmus may be present as well.

Approximately 45 to 60% of all childhood brain tumors arise in the brainstem or cerebellum and can be manifested with slowly progressive ataxia. Acute decompensation can occur with the development of hydrocephalus or hemorrhage into the lesion.

Head injuries with cerebellar contusion or hemorrhage can cause ataxia. In patients with neck injuries, ataxia can be caused by vertebral artery dissection. Posterior circulation strokes are rare in children but should be considered after neck trauma with possible vertebral artery dissection as a cause of the ataxia.

The opsoclonus-myoclonus syndrome consists of ataxia, rapid chaotic multidirectional eye movements, and myoclonic jerks of the extremities, head, trunk, and face. Most commonly, this is seen as a presenting manifestation of neuroblastoma or ganglioneuroblastoma in which the ataxia is thought to be due to a paraneoplastic autoimmune phenomenon involving cross-reactivity of tumor and cerebellar antigens. Spontaneous vertebral artery dissections also have been reported in children without a known history of trauma.[78]

Ataxia can be seen in patients with basilar migraine and can be associated with vertigo, hemiparesis, cranial nerve dysfunction, nausea, vomiting, or headache.[78]

Loss of sensory input to the cerebellum can cause a sensory ataxia. Clinical manifestations will include a Romberg sign, decreased deep tendon reflexes, and impaired proprioception and vibration sense. Fifteen percent of patients with Guillain-Barré syndrome have sensory ataxia. In the Miller Fisher variant of Guillain-Barré syndrome, the triad of ataxia, areflexia, and ophthalmoplegia of vertical gaze is characteristic.[78]

Transient ataxia can be present in the ictal or postictal phase of seizures. Inborn errors of metabolism also can be manifested with ataxia, which can develop acutely or be intermittent, depending on dietary intake or the presence of other illness. Such disorders should be considered when ataxia is accompanied by lethargy, encephalopathy, vomiting, diarrhea, or unusual body odor. Defects in urea acid cycle enzymes called aminoacidurias as well as defects in pyruvate and lactate metabolism can cause such signs and symptoms. Other inherited disorders, such as Niemann-Pick, Tay-Sachs, and Wilson's diseases, also can cause ataxia. Repeated attacks of ataxia also can be the presenting manifestation of multiple sclerosis.

A discussion of all of the genetic disorders that can cause ataxia is too vast to be included here, but the two most common genetic disorders are Friedreich's ataxia and ataxia-telangiectasia.

Friedreich's ataxia is a disorder of autosomal recessive inheritance characterized by progressive gait and limb disturbance. It is caused by mutation in the gene encoding a mitochondrial protein, frataxin, that results in loss of gene function. Affected patients demonstrate dysarthria, lower limb areflexia, proprioceptive sensory loss, and high-arched feet (pes cavus). Most patients are unable to walk by the age of 30 years. Death is most commonly due to cardiomyopathy, causing intractable congestive heart failure, and respiratory compromise from severe kyphoscoliosis.[78]

Ataxia-telangiectasia is a disorder of recessive inheritance caused by gene mutation manifested as a truncal ataxia in infancy that leaves most patients wheelchair bound by the age of 12 years. Oculocutaneous telangiectasias usually appear by the age of 3 to 5 years. These patients also demonstrate dysarthria, nystagmus, dystonic posturing, myoclonic jerks, and accelerated aging. They have deficient immunoglobulin A and decreased immunoglobulin E and M levels. They suffer from frequent sinus and pulmonary infections and have a 50- to 100-fold risk for development of leukemia and lymphoma. The mean age at death from this disorder is 20 years.[80]

Diagnosis

The key to making the diagnosis is to take a complete history and to perform a thorough physical examination. In particular, testing of cerebellar function can be accomplished by assessment of the child for dysmetria and dysdiadochokinesia.[81] Urine and serum toxicologic studies are the laboratory tests most likely to prove diagnostic. CT and MRI findings usually are normal in patients with postinfectious ataxia, but demyelination, tumor, hydrocephalus, or traumatic injuries may be identified. CSF analysis may show mild pleocytosis or lymphocytosis in acute postinfectious ataxia; findings are normal in most other cases. Electroencephalography is recommended for patients with altered consciousness and fluctuating clinical signs. A pattern of epileptiform discharges or slowing is seen in 66% of children with acute cerebellar ataxia. Electroencephalography also can diagnose nonconvulsive or convulsive seizures. The electroencephalographic pattern is normal in the opsoclonus-myoclonus syndrome. Electromyography may be helpful if sensory ataxia is suspected and may help diagnose Guillain-Barré syndrome. Urinary catecholamines can be assayed for diagnosis of neuroblastoma. Testing for newborn errors of metabolism includes a CBC; liver function tests; measurement of blood ammonia, lactate, pyruvate, and ketone levels; and determination of acid-base status. Other tests include plasma and urinary amino acid assays, urine organic acid assay, determination of serum biotinidase level, and CSF lactate assays. Genetic or other specialized testing also may be required. In the absence of developmental delay or positive family histories, however, these investigations for inborn errors of metabolism are unlikely to be helpful.[81]

Management

Children with ataxia usually require hospital admission for a complete evaluation. Consultation with a pediatric neurologist should be sought for patients in whom the cause of the ataxia is not evident on the ED evaluation.

Most children with acute cerebellar ataxia recover completely. Improvement is seen within a week and complete recovery in 3 months for 50% of children. Sixty-six percent to 90% recover completely. Some children exhibit persistent gait disturbances, ataxia, and delayed speech development. Evidence is lacking for improved outcomes with immunosuppressive therapies. Recovery is slower from acute postinfectious demyelinating encephalopathy. Corticosteroids may hasten recovery. Relapse can occur in up to

www.ketabpezeshki.com 66485457-66963820

10% of children. Most children recover fully, but some are left with significant permanent sequelae. Brainstem encephalitis should be treated with broad-spectrum antibiotics effective against *L. monocytogenes;* acyclovir should be included to provide coverage for varicella and other viruses until an organism is discovered. Patients with Guillain-Barré syndrome will need to be hospitalized and may require intravenous immune globulin and plasmapheresis to reduce circulating antibodies.

PEDIATRIC VERTIGO

Perspective

Vertigo is defined as an illusion of movement, a sensation that the external world is revolving around an individual (objective vertigo) or that the affected person is revolving in space (subjective vertigo). Vertigo is well recognized to occur in the pediatric age group and has many potential causes.

Pathophysiology

Disease processes that affect the balance of the vestibular, visual, and proprioceptive systems can cause vertigo by impairing the neural activity of the vestibular nucleus. Diseases of the ear, the eighth cranial nerve, the neck, the brainstem, or, rarely, the eye can lead to vertiginous symptoms. Vertigo is characterized as *central* or *peripheral,* depending on whether the cause is in the CNS.

Clinical Features

Vertigo often is manifested with dizziness. There may be a history of sudden falls, grasping for support, or unwillingness to move. Review of symptoms should include those related to the ear, such as otalgia, hearing loss, and tinnitus. Other important historical features that should be asked about include headache, loss of consciousness, head trauma or barotrauma, and family history of migraine and seizure disorders.

Diagnostic Strategies

For determination of the cause of vertigo, patients can be divided into those who have hearing loss and those who have normal hearing. In the group with hearing loss, further characterization of the loss as conductive or sensorineural in character and identification of the presence of trauma, and whether the causative disorder involves the CNS or the peripheral nervous system from the labyrinth or eighth cranial nerve, will help in diagnosis (Fig. 175-2).

Differential Considerations

Although vertigo is not as common in the pediatric age group as in adults, it has many potential causes (Box 175-17).[82] It usually is helpful to separate those conditions that cause vertigo into those with and those without associated hearing loss.

Box 175-18 Causes of Vertigo with and without Hearing Loss

Hearing Loss
Conductive
Otitis media with effusion
Chronic suppurative otitis media or cholesteatoma should be considered

Sensorineural
Perilymphatic fistula
Tumor
Ménière's disease
Migraine headache
Genetic syndromes
Temporal bone fracture
Vestibular concussion

No Hearing Loss
Acute Vertigo
Perilymphatic fistula
Benign positional vertigo
Seizure
Labyrinthitis

Recurrent or Chronic Vertigo
Acoustic neuroma
Multiple sclerosis

Benign paroxysmal vertigo of childhood is defined by the repeated occurrence of vertiginous episodes lasting seconds to minutes, with occasional vomiting. This entity usually remits spontaneously within months to years. The most frequent cause of benign paroxysmal vertigo of childhood is a migraine headache,[80] with vertigo occurring as the aura of an episode.

Patients with basilar artery migraines also present with vertigo; hemiparesis; ataxia; palsies of the third, sixth, or seventh cranial nerve; drop attacks; and blindness in various combinations followed by migraine headache. Children with benign paroxysmal vertigo of childhood or basilar migraines usually have a family history of migraine headaches.

Benign positional vertigo is rare in children, and the earliest age at which it has been reported is 11 years. It is believed to be due to an otolith that has moved out of its normal position in the utricle and can occur spontaneously as well as after trauma.

Ménière's disease, a syndrome with a combination of vertigo, fluctuating hearing loss, and tinnitus, is responsible for 1.5 to 4% of cases of pediatric vertigo.[83,84]

Vestibular neuronitis is manifested with vertigo without hearing loss. A viral infection is thought to be the cause. Sixty percent of patients have a preceding cold. It is manifested with severe vertigo that resolves in a few days, after which the child will have vertigo only with rapid head movements, which persists for weeks or months until central compensation occurs.[85]

Labyrinthitis is an inflammatory process involving the inner ear membranous labyrinth. It is manifested with vertigo, hearing loss, and tinnitus. Viruses such as cytomegalovirus, rubella virus, and rubeola virus are etiologic agents. Bacterial labyrinthitis also can occur, usually in association with meningitis. Lyme disease and syphilis may cause vertigo if the inner ear is affected.[86] Neurofibromatosis can be manifested with vertigo if it involves the superior vestibular nerve; café au lait spots should be looked for. Other genetic syndromes also are associated with vertigo (see Box 175-17).[86]

Ototoxic drugs, such as aminoglycosides and chemotherapeutic drugs, can be a cause of vertigo, usually in association with hearing loss (Box 175-18). Cerebellar and brainstem lesions on occasion also are manifested with vertigo. Cranial nerve deficits associated with vertigo may indicate a lesion or tumor.[85,86]

Multiple sclerosis can have vertigo as one of the symptoms, and vertigo is the presenting symptom in 5 to 12% of cases. Endocrine disorders, such as thyroid disease and diabetes mellitus, have rarely been reported to cause vertigo.

In post-traumatic vertigo, disturbances of cochlear and vestibular functions are the most common etiology of late-onset vertigo from head injury in children. If labyrinthine damage is caused by trauma (labyrinthine concussion), vertigo, gait unsteadiness, and swaying toward the affected side are present along with nausea and vomiting. Symptoms and signs subside during a period of 4 to 6 weeks. Signs of vestibular dysfunction may be present many years after the injury. Positional nystagmus with the quick component toward the uninvolved side usually is present. Vestibular concussions can cause vertigo without hearing loss after a blow to the parietal-occipital or temporal-parietal region. It normally is continuous for several days, followed by improvement, but it may recur intermittently with certain head positions. Displacement of an otolith is thought to be responsible.[87]

Temporal bone fracture (especially transverse) may cause vertigo by injury to the eighth cranial nerve or the otic capsule; it also may cause sensorineural hearing loss.[87] Whiplash injuries to the neck also can cause vertigo; up to 50% of patients experience hearing loss or tinnitus. Post-traumatic migraine and seizures also can cause vertigo and occur in 5 to 7% of patients with closed head injuries.[88]

Perilymphatic fistula is manifested with sensorineural hearing loss of sudden onset. It frequently is associated with congenital

www.ketabpezeshki.com 66485457-66963820

cranial deformities and congenital abnormalities of the ear. However, barotrauma (flying, extreme coughing, retching, or straining) or direct trauma also can be a cause. There is leakage of fluid from the oval or round window into the middle ear. Having the patient perform a Valsalva maneuver may precipitate vertigo. Hennebert's sign, which consists of nystagmus and vertigo after negative pressure is induced in the ear by a pneumatic otoscope, may be a feature.[85] Treatment usually consists of surgical repair.

Ocular disorders, such as convergence insufficiency, strabismus, and amblyopia, have been reported to cause a sensation of vertigo. Treatment of these disorders will eliminate the vertigo in children.[87]

Diagnostic Strategies

For most patients, the final diagnosis for the cause of the vertigo may not be able to be made in the ED. A complete physical examination, including otologic and neurologic evaluation, is important. Looking for nystagmus and cerebellar testing are especially critical. Having the child hop as well as stand from a seated position on the floor with eyes open and closed may reveal vestibular dysfunction. Looking for physical signs of other disease processes, such as café au lait spots in neurofibromatosis, may aid in diagnosis. If a Valsalva maneuver or the Hennebert maneuver initiates vertigo, the cause probably is a perilymphatic fistula.

Vertical nystagmus is usually from a central cause. Nystagmus from peripheral causes tends to be extinguished or to diminish after rapidly repeated stimulation, whereas central nystagmus does not. Helpful laboratory tests in the vertiginous patient include glucose and electrolyte assessment, thyroid function tests, and viral titers or serologic studies (e.g., for Lyme disease or syphilis), as the physical examination dictates.[86] The Hallpike-Dix positioning maneuver may help diagnose benign positional vertigo.[85] A CT or MRI scan is indicated only in cases of central vertigo.

Management

Management of the vertiginous patient depends on the underlying cause, which may not be evident in the ED.[89] For acute symptomatic relief, vestibular suppressants such as meclizine and diazepam may be helpful. Otoliths causing inappropriate stimulation may be restored to their proper place by Epley's maneuver.[82] Vestibular rehabilitation exercises that encourage patients to move the head while viewing a stimulus may assist in vestibular adaptation and reduce symptoms. Follow-up, including examination, testing, and treatment by a neurologist or an otolaryngologist for vertiginous patients, is recommended.[90] Highly symptomatic children may need to be admitted to the hospital.

SYNCOPE

Perspective

Syncope is defined as a sudden, reversible, typically brief loss of consciousness and muscle tone (between 20 and 60 seconds) with spontaneous and complete recovery after a brief duration. Presyncope is defined as having a sensation of passing out but remaining conscious with a transient loss of postural tone. The exact incidence of syncopal episodes is not known, but 15 to 25% of children and adolescents experience one episode by young adulthood.[91] The peak incidence occurs between 15 and 19 years of age, and females are affected more frequently than males. The presentation of these events can be frightening to the patient and those who witness them. Gordon and co-workers found that in a group of pediatric patients presenting to the ED, a mean of six diagnostic tests were performed per patient, 40% of these patients were admitted to the hospital, and total charges averaged $3000 per patient, yet significant pathologic conditions were found in less than 10% of the patients.[92]

Principles of Disease

The causes of syncope can be divided into autonomic, cardiac, and noncardiac. The most common cause of syncope is reflex syncope (also called autonomic, vasovagal, neurocardiogenic, or vasodepressor syncope or fainting). Venous pooling and decreased preload associated with prolonged standing normally are compensated by reflex tachycardia and increased sympathetic tone. However, patients with vasopressor syncope who are prone to syncope demonstrate a cardioinhibitory response causing bradycardia or a vasodepressor response causing hypotension or, most commonly, a combination of both. Patients with cardiac syncope have decreased cerebral blood flow resulting from poor cardiac filling or contractility, elevated afterload, or cardiac arrhythmias.

Clinical Features

Patients can experience syncope during intercurrent illnesses, with mild dehydration, during menstruation, or after vigorous exertion. In those with situational syncope, typical triggers may include emotion, pain, hyperventilation, shower, cough, swallowing, urination, or defecation. Before the event, they may experience dizziness, lightheadedness, weakness, nausea, chest discomfort, palpitations, blurred vision, headache, tremulousness, and anxiety. After the event, loss of consciousness is brief (usually for less than 20 seconds), and the patient is described as ashen appearing, with sweating and coolness of the extremities.[93] Other examples of conditions associated with neurally mediated syncope are postural orthostatic tachycardia syndrome, chronic fatigue syndrome, and pandysautonomia.[94] Patients with postural orthostatic tachycardia syndrome and pandysautonomia experience orthostatic palpitations rather than straightforward syncope, do not appear healthy between events, and complain of fatigue and exercise intolerance. Patients with pandysautonomia also exhibit thermoregulatory impairment, sweating, and bowel dysfunction. Although cardiac causes of syncope are rare, they can be life-threatening and should be suspected when the episode occurred during exercise or physical activity. Noncardiac causes include seizures. Helpful features to differentiate seizures from syncope include the following: seizures usually occur in a supine rather than in an upright position; convulsions occur before rather than after the loss of consciousness; and warm, flushed, or cyanotic-appearing skin, rather than pale and sweaty skin, is characteristic.

Diagnosis

Evaluation of the patient begins by obtaining a description of the event, previous episodes, and past personal and family history. A detailed description of the event and particular note of any presyncopal symptoms or signs, such as sweating, nausea, pallor, visual changes, or onset with a rapid change in position, can suggest vasovagal syncope. A thorough physical examination including a detailed neurologic examination is essential. A baseline electrocardiogram should be obtained to rule out structural heart disease or an arrhythmia. If the history, physical examination, and electrocardiogram are typical for a neurally mediated event, further testing is not usually required. Additional testing is warranted with family history of sudden death, early infarction, or arrhythmia; previous personal history of fatigue with a known arrhythmia or heart defect; syncope preceded by chest pain or palpitations; occurrence of syncope during exercise; occurrence of syncope without a prodrome; recurrent syncope (more than two or three episodes); and a syncopal event with neurologic sequelae.[95]

www.ketabpezeshki.com 66485457-66963820

Differential Considerations

Cardiac causes of syncope may be life-threatening. Such disorders include underlying structural abnormalities of the heart, such as cardiomyopathies (hypertrophic, dilated, and restrictive), postoperative congenital heart anatomic changes (Mustard, Fontan), congenital coronary artery abnormalities, myocarditis, aortic and subaortic stenosis, and pulmonary hypertension. Other cardiac abnormalities include those classified as electrical disorders, such as prolonged QT syndrome, Wolff-Parkinson-White syndrome, atrioventricular block, idiopathic ventricular fibrillation, and Brugada syndrome. Patients with an underlying cardiac abnormality merit further investigation, which may include 24- to 48-hour Holter monitoring, echocardiography, or exercise stress testing. Tilt-table testing can be used after diseases such as myocarditis, hypertrophic cardiomyopathy, and long QT syndrome have been ruled out because such testing in this subgroup can have fatal consequences.

Common noncardiac causes of syncope include neurologic disorders (seizures, migraines, tumor, and vertigo), breath-holding spells, electrolyte abnormalities (hypoglycemia), hyperventilation (hypocapnia), endocrinopathies, toxins (carbon monoxide), and drugs of abuse.

Management and Disposition

Syncope is a common pediatric problem and usually has a benign, neurally mediated cause. Patients with a potential serious cause, such as a cardiac or neurologic condition, should be treated and admitted.[95] Certain groups of patients may have an increased risk for cardiac syncope and should eventually be referred to a pediatric cardiologist for evaluation. These include athletes, patients with eating disorders or chronic fatigue, persons who use illicit substances, and survivors of congenital heart disease. Athletes with suspected hypertrophic cardiomyopathy, aortic stenosis, or other potentially critical cardiac conditions should be restricted from exercise until they are evaluated by a cardiologist.[91]

The approach to management of patients with neurocardiogenic syncope is primarily one of education, involving avoidance of potential triggering events (hot, crowded environments; volume depletion) and recognition of the early signs and symptoms to allow timely maneuvers to abort the syncopal episode (e.g., assumption of a supine position, ingestion of fluids, leg crossing). The patient and the family should be reassured that these events are not life-threatening. A simple approach is to encourage liberal fluid intake and to increase dietary salt intake. In a subgroup of patients with recurrent syncope or recurrent dizziness, however, a trial of an appropriate medication may be warranted. No large pediatric randomized studies have been conducted to investigate this application of such medications, which include beta-blockers, fludrocortisone, selective serotonin reuptake inhibitors, and alpha-agonists.[96]

KEY CONCEPTS

- Signs and symptoms of bacterial meningitis vary by age and can include nonspecific manifestations, such as irritability and lethargy, in infants and young children.
- A careful and detailed history is instrumental in determining whether an event was a seizure. If the event was a seizure, the history should delineate what type of seizure occurred (partial or generalized) and whether the clinical event fits into a known epilepsy syndrome.
- Status epilepticus constitutes a neurologic emergency that carries high morbidity and mortality rates. Usual initial treatment is with lorazepam followed by fosphenytoin or phenytoin.
- For patients experiencing a febrile seizure, ED management should include a review with family members of appropriate first aid, use of antipyretics, recurrence risk and risk for epilepsy, and follow-up care with the child's primary care physician.
- The possibility of acute symptomatic, or provoked, seizures should be considered, particularly because many of the causes of such seizures are treatable.
- A majority of headaches in children have benign causes that usually can be diagnosed by a careful history and physical examination.
- Radiologic evaluation by CT or MRI, or both, may be necessary to rule out secondary causes of headache, such as intracranial hemorrhage, subarachnoid hemorrhage, brain abscess, and brain tumor.
- A toxicology screen is the test with the highest diagnostic yield for acute-onset ataxia in children. The most common cause of benign positional vertigo in children is a migraine headache. The etiology of vertigo with hearing loss is significantly different from that of vertigo with no hearing loss.
- Most children with ataxia require hospitalization for evaluation and diagnosis.

CHAPTER 176

MUSCULOSKELETAL DISORDERS

Kemedy K. McQuillen

PERSPECTIVE

Each year there are more than 11 million pediatric injury-related emergency department (ED) visits, 14.3% of which are due to fractures and dislocations.[1]

As a result of the physiologic and anatomic differences between children and adults, pediatric patients are susceptible to problems that do not affect the adult population. An understanding of these differences helps the emergency physician appropriately diagnose and treat musculoskeletal complaints in children. This chapter reviews the general principles and physiology of the pediatric musculoskeletal system, highlights the more common pediatric fractures, and describes musculoskeletal problems specific to the pediatric population.

PRINCIPLES OF DISEASE

Anatomy and Physiology

Several factors distinguish the pediatric musculoskeletal system from that of the adult. The most striking difference is the presence of a physis or growth plate. The physis is made up of proliferating cartilage cells between the metaphysis and epiphysis. Because it is composed of cartilage, the growth plate is the weakest part of the bone and is more likely to separate before the adjacent tendon or ligament tears. Accordingly, sprains are less frequent in the pediatric population than in the adult population, and physeal injuries are common.

Another factor that influences pediatric musculoskeletal injuries is the presence of a thick, physiologically active periosteum that is easily stripped from the bony cortex. When injuries occur, the periosteum often is torn on the convex side (i.e., the reverse aspect of a bone subjected to a deforming force) while remaining intact on the concave side (the aspect directly incurring the force of injury). In any case, the periosteum acts as a tether to reduce the amount of fracture displacement and, when it remains intact, aids in fracture reduction. The great bone-forming potential of the periosteum also facilitates the healing process; callus formation is vigorous, and nonunion almost never occurs.

Growing bone is more porous, more pliable, and less dense than adult bone. These characteristics result in less strength, thus making children more susceptible to fractures. However, although it takes less force to cause deformation, pediatric bone is more likely to buckle when it is compressed or to bow when it is bent. Finally, because the bones are still growing, the potential for remodeling is greater with metaphyseal fractures. Growth can compensate for postreduction imperfections in both apposition and alignment, with deformities occurring in the plane of motion having the greatest potential for remodeling.

Fracture Patterns

As with fractures in adults, description of pediatric fractures includes the bone location (diaphysis, metaphysis, physis, or epiphysis), configuration, relationship of fracture fragments to one another (angulation and displacement), and relationship of fracture fragments to adjacent tissue (open or closed). The inherent differences between pediatric and adult bone result in fracture configurations that are not found in the adult population. Pediatric fractures can be classified as follows:

- Plastic deformation: Bone is bowed with no obvious cortical disruption.
- Torus fracture (buckle fracture): Buckling of bone without cortical disruption tends to occur because of compression failure of the bone at the metaphyseal-diaphyseal junction (Fig. 176-1). These fractures may be immobilized with a splint or cast or, if they involve the distal end of the radius, a Velcro wrist splint[2] or backslab.[3] The splint or backslab can be removed by the family or primary care provider in 3 to 4 weeks, thereby obviating the need for orthopedic follow-up. Children treated with removable splints also had less pain, improved function, and fewer unscheduled ED visits because of problems with the cast.[4] Buckle fractures also may be treated with a soft cast[5,6] or a plaster splint.[7]
- Greenstick fracture: Bone and one cortex are disrupted; the periosteum on the fracture's compression side remains intact (Fig. 176-2). Some authors recommend immobilization of minimally angulated (<15 degrees) distal radius greenstick fractures with splints[8]; others contend that casting is necessary because of continued fracture displacement during the first 2 weeks of healing.[9]
- Complete fracture: The fracture propagates completely through the bone; included are transverse (Fig. 176-3), spiral (Fig. 176-4), oblique, and comminuted (Fig. 176-5) fractures.

The relatively weak cartilaginous physis in growing bone makes physeal injury common in the skeletally immature. Although injuries to the physis can occur at any age, they are more common during rapid skeletal growth. The Salter-Harris classification system is the most frequently used tool to describe physeal injuries. This classification system is based on the extent of involvement of the physis, epiphysis, and joint (Table 176-1). Types I and II Salter-Harris injuries (Figs. 176-6 and 176-7) do not involve the germinal layer of the growth plate; therefore, the risk for growth arrest is small. In general, the higher the Salter-Harris classification (Salter-Harris types III to V), the greater the damage to the growth plate and the greater the likelihood of growth arrest or limb-length abnormalities (Figs. 176-8 to 176-10). Type II fractures are the most common Salter-Harris injury and account for approximately three fourths of all growth plate injuries.

Type I	Fracture extends through the physis (see Fig. 176-6)	Type II	Fracture extends from the physis into the metaphysis (away from the joint space) (see Fig. 176-7)	Type III	Fracture extends from the physis into the epiphysis (toward the joint space) (see Fig. 176-8)	Type IV	Fracture extends from the physis into the metaphysis and epiphysis (see Fig. 176-9)	Type V	Crush injury of the physis (see Fig. 176-10)	
SPECIFIC DISORDERS

Clavicle Fracture

The clavicle is one of the most frequently broken bones in children. The physis of the clavicle does not close until the age of 23 to 25 years and is at risk for injury until that time. Midshaft fractures account for approximately 85% of all clavicle fractures; distal and proximal fractures account for approximately 10% and 5%, respectively. The usual mechanism of injury is a fall on the shoulder or, less commonly, direct trauma to the bone itself. The child typically supports the affected side with the other hand and tilts the head toward the side of the fracture. Physical examination reveals point tenderness at the fracture site, with or without an obvious bone deformity. With a minimally displaced fracture, shoulder motion may be tolerated. Otherwise, range of motion of the shoulder is limited by pain. Although complications are rare, the proximity of the clavicle to the great vessels and brachial plexus calls for a thorough neurovascular evaluation; severe posterior sternoclavicular displacement can cause injury to the trachea, esophagus, and subclavian vessels; lateral clavicular displacement can result in injury to the brachial plexus. Middle third fractures have been associated with neurovascular bundle injuries, pulmonary injury, and pneumothorax.

An anteroposterior (AP) radiograph of the clavicle (Fig. 176-11) confirms the diagnosis. If clinical suspicion is high and the AP view does not reveal a fracture, a 30-degree cephalic view can be helpful. Specialized imaging studies are rarely needed, although

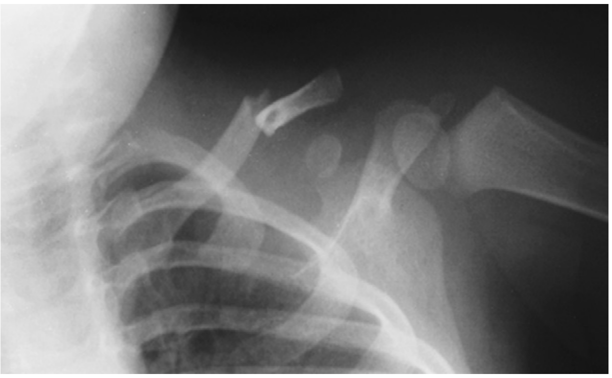

Figure 176-11. Fracture of the middle third of the clavicle.

computed tomography (CT) and duplex ultrasonography may be considered with proximal, posteriorly displaced fractures or dislocations to evaluate for the aforementioned complications.[10]

Clavicle fractures usually do not require anatomic reduction for healing or function; therefore, treatment is typically directed at maintenance of comfort with splinting, ice, and analgesics. Figure-of-eight splinting helps bring the clavicle out to length, relieves muscle spasm, and minimizes motion at the fracture site. Immobilization with the figure-of-eight splint, previously the treatment of choice, has fallen out of favor because of the risk for brachial plexus palsy with long-term use. Alternatively, a sling with or without a swath can be used to provide comfort by supporting the upper extremity and relieving the suspensory forces usually maintained by the clavicle. Most clavicle fractures heal without any problems, except for the development of bony callus at the fracture site; the younger the patient, the greater the potential for remodeling of this deformity. As the fracture stabilizes and the comfort level improves, range-of-motion exercises can be started, with gradual progression in intensity. Younger children generally require shorter periods of immobilization (2-4 weeks) than those used in adolescents and adults (4-8 weeks). Rehabilitation includes early range of motion and strengthening of the rotator cuff. Patients may return to contact sports when there is no tenderness at the fracture site or pain with range of motion and they have achieved normal strength.

Although surgical intervention is uncommon with clavicle fractures, immediate orthopedic consultation should be obtained for fractures that are open or associated with neurovascular compromise or for fractures that are associated with more than 100% displacement of the fracture fragment with severe skin tenting. In addition, distal clavicular fractures in general and middle clavicular fractures that are severely comminuted or displaced more than 20 mm may also require surgical management, and these patients should be seen by an orthopedic surgeon within 72 hours. High-level athletes should also be referred to an orthopedist for surgical evaluation as surgical repair may expedite their return to sports.

Clavicle fractures also can occur during childbirth and represent more than 90% of obstetric fractures. They occur equally in boys and in girls and on the right and on the left sides. Displaced clavicle fractures are identified by crepitus, edema, lack of movement of the affected extremity, asymmetrical bone contour, and crying with passive motion in the immediate period after delivery. Nondisplaced asymptomatic fractures may not be noticed until 10 days of age, when the bony callus becomes apparent. The diagnosis is made by radiographs of the chest, clavicle, and upper extremity; these radiographs help differentiate clavicle fractures from traumatic separation of the proximal humeral epiphysis, humeral shaft fractures, and dislocations of the shoulder, all of which may be manifested with similar findings. In addition, the presence of a clavicle fracture warrants further investigation for accompanying brachial plexus injury.

Table 176-2 Gartland Classification of Extension-Type Supracondylar Fractures

Type I	Nondisplaced fracture
Type II	Displaced fracture with intact posterior cortex
Type III	Displaced fracture with no cortical contact A: Posteromedial rotation of the distal fragment B: Posterolateral rotation of the distal fragment

Modified from Gartland JJ: Management of supracondylar fractures of the humerus in children. Surg Gynecol Obstet 109:145, 1959.

Supracondylar Fractures of the Humerus

Supracondylar fracture is the most common elbow fracture in the pediatric population. Most such fractures are sustained in children younger than 8 years. Until that age, the tensile strength of the ligaments and joint capsule is greater than that of the bone itself; the weaker bone therefore yields to the stronger ligament complex around the joint.

Supracondylar fractures are classified as flexion or extension according to mechanism of injury. The extension type of fracture constitutes 95% of all supracondylar fractures and typically results from a hyperextension injury to the elbow incurred in a fall onto the outstretched arm. In this injury, the olecranon is forcefully driven into the olecranon fossa, and the forces are concentrated in the supracondylar area. This mechanism results in failure of the anterior cortex and displacement of the distal fragment posteriorly. With extension-type supracondylar fractures, the degree of displacement and continuity of the cortex are further defined by the Gartland classification[11] (Table 176-2). In the less common flexion type of supracondylar fracture, the elbow is flexed when it hits the ground, and energy is transferred from the posterior aspect of the proximal end of the ulna to the distal end of the humerus. This mechanism results in a supracondylar fracture with anterior displacement of the distal fragment and failure of the cortex posteriorly.

Children with supracondylar humerus fractures may present with anything from mild swelling and elbow pain to a grossly displaced humerus. Gentle palpation is useful to determine the site of injury; however, manipulation should be avoided because movement may cause further neurovascular damage. Children with extension-type supracondylar fractures hold the affected arm in extension with an S-shaped configuration of the elbow and exhibit a prominence at the olecranon. Children with flexion-type supracondylar fractures hold the arm in flexion and exhibit an empty space where the olecranon should be. In all cases it is important to carefully assess distal neurovascular status. Motor and sensory function should be evaluated by assessment of the radial, ulnar, and median nerves (Table 176-3). Two-point discrimination on the fingers provides a sensitive means of assessing sensory status: an abnormal value (>5 mm) indicates a deficit. Vascular assessment should include evaluation of radial and brachial pulses and capillary refill of the hand. Patients with displaced fractures should have ongoing assessment for the development of compartment syndrome of the forearm. With pain on flexion or extension of the fingers, forearm swelling, tenseness or tenderness, or pain that is disproportionate to the injury, compartment pressures should be measured immediately. Unrecognized ischemic injury can result in Volkmann's ischemic contracture, which is characterized by fixed elbow flexion, forearm pronation, wrist flexion, metacarpophalangeal joint extension, and interphalangeal flexion.

Table 176-3 Neurologic Examination of the Distal Upper Extremity

	EXAMINATION COMPONENT	
NERVE	Motor	Sensory
Radial	Wrist extension	Thumb and first finger web space
Ulnar	Wrist flexion and adduction	Little finger
Median	Wrist flexion and abduction Thumb opposition	Thumb, index, and middle fingers Radial aspect of palm of hand
Anterior interosseous	Distal phalanx flexion (thumb and first finger)	None

Table 176-4 Sequence of Ossification around the Elbow: CRITOE

OSSIFICATION CENTER	AGE AT APPEARANCE	AGE AT CLOSURE
Capitellum	6-12 months	14 years
Radial head	4-5 years	16 years
Medial (Internal) epicondyle	5-7 years	15 years
Trochlea	8-10 years	14 years
Olecranon	8-9 years	14 years
Lateral (External) epicondyle	9-13 years	16 years

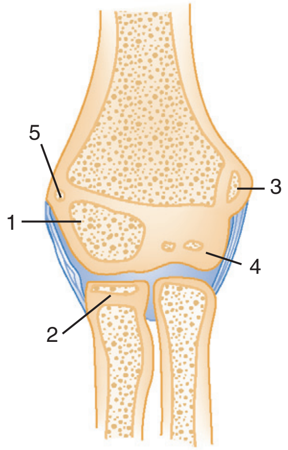

Figure 176-12. Ossification centers of the elbow: *1,* capitellum; *2,* radial head; *3,* medial epicondyle; *4,* trochlea; *5,* lateral epicondyle. (From Connolly JF: DePalma's Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)

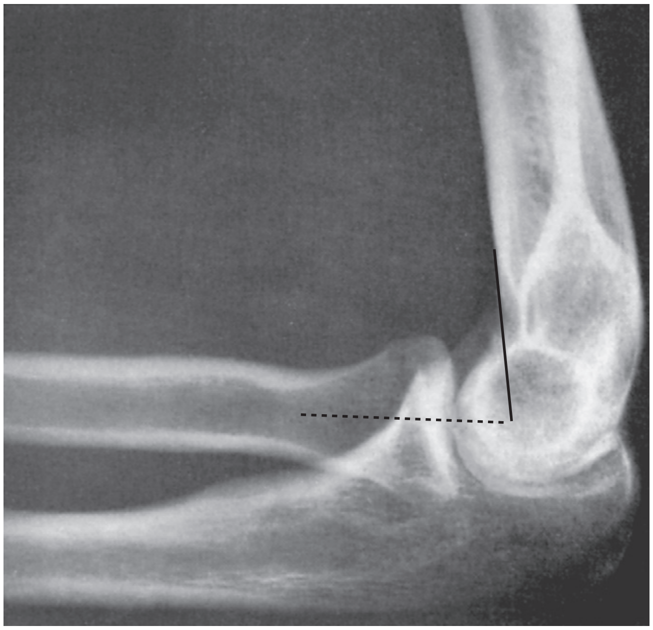

Figure 176-13. Lateral radiograph demonstrating the bone relationships in a normal elbow. The anterior humeral line (*solid*) and proximal radial line (*dashed*) bisect the capitellum. (From Weissman BN, Sledge CB: Orthopedic Radiology. Philadelphia, WB Saunders, 1986.)

Radiographic evaluation of any elbow injury should include an AP view of the extended elbow and a lateral view of the flexed elbow. If these views do not show a fracture but clinical suspicion is high, oblique views are helpful. Even with proper radiographs, diagnosis of a pediatric elbow fracture can be difficult. The elbow is largely cartilaginous during early childhood, and the six secondary centers of ossification around the elbow can camouflage or be mistaken for fractures (Fig. 176-12). These ossification centers can be remembered by the mnemonic CRITOE: capitellum, radius, internal (medial) epicondyle, trochlea, olecranon, and external (lateral) epicondyle. The approximate ages at which these sites ossify may be estimated at 1, 3, 5, 7, 9, and 11 years, respectively (Table 176-4).

Bone relationships are helpful in evaluation of a radiograph for a supracondylar fracture (Fig. 176-13). A true lateral view should demonstrate a figure-of-eight appearance of the distal humerus with bisection of the capitellum by the anterior humeral line. If the capitellum falls posterior to this line, an extension-type supracondylar fracture is likely. In all views, the proximal end of the radius and radial neck should point to the capitellum. Baumann's angle also is helpful in diagnosis of subtle supracondylar fractures[12] (Fig. 176-14). This angle is formed by a line drawn to follow the growth plate of the capitellum transected with a line that runs perpendicular to the axis of the humerus. The angle should be approximately 75 to 80 degrees. Baumann's angle should be the same in both elbows, and differences between elbows can be used

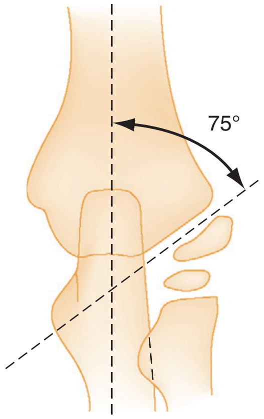

Figure 176-14. Baumann's angle in a normal elbow on an anteroposterior radiograph. (From Worlock P: Supracondylar fractures of the humerus: Assessment of cubitus varus by the Baumann angle. J Bone Joint Surg Br 68:755, 1986.)

www.ketabpezeshki.com 66485457-66963820

Figure 176-15. Lateral radiograph of a supracondylar fracture with an anterior fat pad "sail sign" and a posterior fat pad.

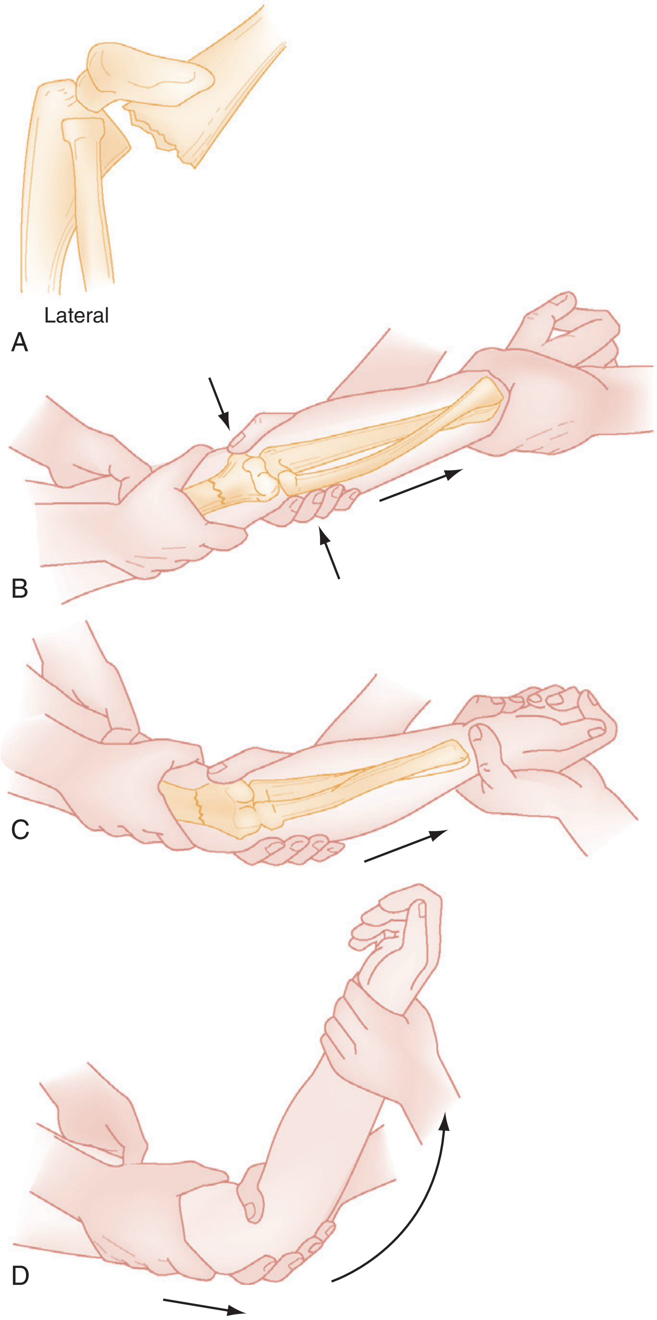

Figure 176-16. Steps in reduction of a displaced supracondylar fracture, seen in **A**. **B,** The assistant fixes the arm of the patient while the physician grasps the patient's wrist and applies steady traction in line with the long axis of the arm while keeping the forearm in the neutral, thumb-up position. **C,** If the distal fragment is displaced laterally, it is pushed inward with the physician's other hand. If it is displaced medially, it is pushed outward. Throughout manipulation, traction is maintained. **D,** After length is restored and the medial and lateral displacement is corrected, the physician's thumb is placed over the anterior surface of the proximal fragment with the fingers behind the olecranon, and the elbow is gently flexed. The arm is then immobilized with the forearm pronated; laterally displaced fractures are immobilized with the forearm supinated. (From Geiderman JM, Magnusson AR: Humerus and elbow. In Rosen P, Barkin R [eds]: Emergency Medicine: Concepts and Clinical Practice, 4th ed. St Louis, CV Mosby, 1998.)

to detect subtle supracondylar fractures. In children younger than 3 years, difficult-to-distinguish bone landmarks limit the utility of Baumann's angle. Postreduction alterations in Baumann's angle reliably predict the final carrying angle.[13]

Fat pads also provide a means for detection of occult supracondylar fractures. A lateral radiograph with the elbow flexed at 90 degrees may show an anterior fat pad protruding from the coronoid fossa. This finding is normal unless the pad is bulging or in the shape of a ship's sail. This "sail sign" may indicate fluid in the joint, although alone it may not be a reliable predictor of a fracture. The posterior fat pad, however, sits snugly within the olecranon fossa and should never be seen unless there is a fracture around the elbow. In this case, blood pushes the fat pad laterally, thereby making it visible on a lateral radiograph of the elbow. Accordingly, visualization of a posterior fat pad suggests the presence of an occult fracture around the elbow. The presence of a posterior fat pad without an obvious fracture warrants oblique views of the elbow (Fig. 176-15), splinting, and follow-up.

Plain radiographs usually are sufficient for diagnosis of supracondylar fractures. However, if the diagnosis remains in question after AP, lateral, and oblique radiographs are obtained, ultrasound imaging may be useful in infants,[14] and magnetic resonance imaging (MRI) may be useful in older children.[15]

ED treatment of supracondylar humeral fractures is determined by displacement and neurovascular status. A pale, pulseless cold hand mandates emergency consultation with an orthopedic surgeon. If an orthopedic surgeon is unavailable and the vascular supply has not been restored, reduction should be attempted (Fig. 176-16). If necessary, reduction can be performed by a single operator. With the patient supine, the shoulder held in 90 degrees of forward flexion, and the elbow slightly flexed, both hands are placed on the arm proximal to the fracture, and both thumbs are placed on the posterior aspect of the fracture fragment. Then, while the thumbs are directed distally, the fragment is lifted onto the distal metaphysis. The return of blood supply is marked by the hand's becoming warm and pink. If perfusion does not improve, another reduction may be attempted, with care taken to not entrap the brachial artery and median nerve. Multiple attempts at reduction increase the likelihood of neurovascular injury and swelling; therefore, no more than two reductions should be attempted. If perfusion is not reestablished, the child requires urgent operative

www.ketabpezeshki.com 66485457-66963820

intervention. A supracondylar fracture with a pulseless hand that is warm and pink does not need to be reduced immediately and should be splinted as it lies so that vascular status is not further compromised. The elbow should be splinted in relative extension because too much flexion in conjunction with swelling may obstruct the brachial artery and contribute to limb ischemia.

Gartland type I fractures can be splinted in the ED with the arm maintained in 90 degrees of flexion and neutral rotation. Hospital admission is not required, but these children do require urgent follow-up with an orthopedic surgeon. Gartland type III fractures require immediate orthopedic consultation and should be treated by either closed reduction and percutaneous pinning or open reduction and internal fixation in the operating room. Treatment of a partly displaced type II fracture is controversial. Some surgeons reduce and pin it in the operating room, whereas others perform closed reduction and keep the arm immobilized in a cast. Treatment of displaced supracondylar fractures by closed reduction and casting is associated with higher complication rates than is treatment by closed reduction and pinning; therefore, most such fractures are treated with pinning and casting for 3 to 4 weeks.

The primary complications of supracondylar fractures are related to neurovascular injury. Type III fractures are at greatest risk, with neurovascular compromise occurring in as many as 49% of patients.[16] Neurovascular compromise, however, can occur with any displaced fracture. The median nerve is involved in half of the cases and is associated with posterolateral displacement. The radial nerve is involved in almost one third of patients and is associated with posteromedial displacement. Brachial artery injuries, including arterial entrapment, laceration, intimal tears, thrombosis, and compression from compartment syndrome, occur in approximately 40% of patients and are found with either type of displacement. Fortunately, the brachial artery has many branches around the elbow, and flow to the forearm and hand can be maintained even when the brachial artery is injured.

Despite the frequency of neurovascular deficits immediately after the injury, most nerve palsies are caused by stretching or contusion and resolve spontaneously. The typical course for nerve injuries is complete resolution. Although motor function usually returns within 12 weeks, sensory function may not return for 6 months or longer.[17] If clinical or electromyographic evidence of nerve recovery is lacking after 5 months, exploration and neurolysis are indicated.[18] Volkmann's ischemic contracture (contracture deformity of the fingers, hand, and wrist) and permanent limb disability are the end result of untreated vascular injury. This complication is extremely rare and easily prevented by close observation and evaluation for the development of compartment syndrome. A few supracondylar fractures heal with a "gunstock" deformity; however, the combination of varus, hyperextension, and medial rotation of the limb is not a functional problem and, except in severe cases, requires no treatment. Severe cases can be corrected by humeral osteotomy.

Monteggia's Fracture-Dislocation

Monteggia's fracture-dislocations are characterized by a fracture of the proximal third of the ulna plus dislocation of the radial head. The radiographic evidence can be subtle, with only a minor greenstick fracture or bowing of the ulna. Isolated ulna fractures are rare in children; therefore, with all such fractures, AP and lateral radiographs of the elbow should be obtained to rule out dislocation of the radial head. The radial head should align with the capitellum on all radiographs of the elbow; if it does not, a Monteggia injury should be suspected (Fig. 176-17).

An orthopedic surgeon should be consulted promptly for closed reduction of the radial head dislocation and repair of the ulna fracture. Complications include permanent radial head dislocation, valgus deformity of the arm, loss of pronation, and late radial nerve palsy.

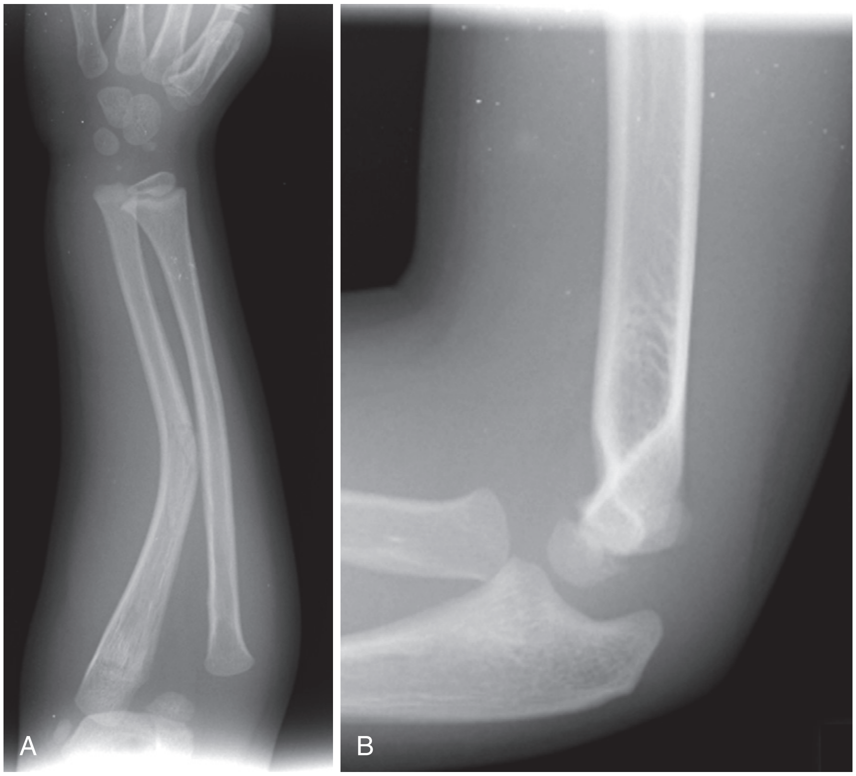

Figure 176-17. A, Anteroposterior view of elbow revealing a distal ulna fracture with radial head dislocation; the radial head should align with the capitellum in all views. B, Lateral view of the elbow demonstrating poor alignment of the radial head with the capitellum consistent with Monteggia's fracture-dislocation. www.ketabpezeshki.com 66485457-66963820

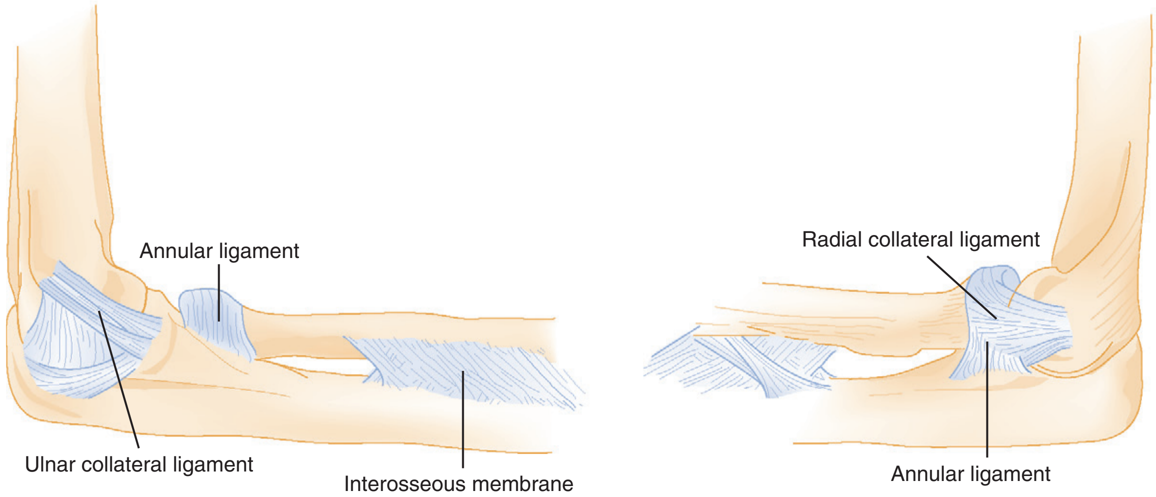

Figure 176-18. Nursemaid's elbow. In a nursemaid's elbow injury, as an axial force is applied, the annular ligament around the radial head is dislodged. The ligament is then partially dislocated into the radiocapitellar joint when the arm is released. (From Simon R, Koenigsknecht S: Emergency Orthopedics: The Extremities, 2nd ed. Norwalk, Conn, Appleton & Lange, 1987.)

Nursemaid's Elbow

In one study, radial head subluxation, or nursemaid's elbow, was the most common upper extremity injury in children younger than 6 years presenting to a pediatric ED.[19] It typically occurs when axial traction is placed on an extended and pronated arm, as when the child is pulled up or swung by the arms. It also may occur when the child falls onto the outstretched arm, sustains minor direct trauma to the elbow, or simply twists the arm. In infants, radial head subluxation can occur when an extended arm is caught beneath the infant's body while being rolled over. In pathoanatomic terms, subluxation occurs when the annular ligament becomes loosened from the head of the radius and slips into the radiocapitellar joint, where it becomes entrapped (Fig. 176-18).

Nursemaid's elbow occurs in children a few months to 5 years of age and has a peak incidence between 2 and 3 years of age.[20] It has been reported in children younger than 6 months[20] and has been seen in children as old as 9 years. This injury has a slight predilection for girls.

The history often includes an event involving a mechanism consistent with the injury followed by acute onset of arm pain that may or may not be localized to the elbow. The affected arm is held against the body, with the elbow slightly flexed and the arm pronated. Physical examination is significant for lack of swelling, erythema, ecchymosis, or deformity. Examination may reveal mild tenderness to palpation of the radial head. Pain is elicited with supination, pronation, and elbow flexion.

The diagnosis of nursemaid's elbow is made clinically, and radiographs are not necessary. If, however, significant point tenderness, swelling, or ecchymosis is present or if the history suggests another injury, such as a supracondylar fracture, radiographs should be obtained. Although it is not commonly used as a diagnostic procedure, ultrasound imaging may demonstrate a widened space between the radial head and the capitellum.[21]

Radial head subluxation is an orthopedic injury that is easily reduced without sequelae. Classically, the affected elbow is gripped with the clinician's thumb over the radial head, and with the other hand, the clinician flexes and supinates the patient's arm. As the radial head relocates, the clinician feels it click or "clunk" under the thumb. Hyperpronation of the forearm also is effective in reducing radial head subluxation. As is done in the flexion-supination maneuver, the child's affected elbow is held with the clinician's thumb over the radial head, but then flexion-supination is replaced with hyperpronation of the forearm. Success rates range from 80[20] to 92%[22] with supination and from 93[23] to 98%[24] with pronation. Pronation also may be less painful to the patient[24,25] and is the reduction method of choice.[24] After successful reduction, the child typically uses the arm normally within 10 minutes. This may be delayed in younger children and when the injury occurred more than 4 to 6 hours before reduction. Neither splinting nor orthopedic referral is required after a successful reduction.

Failure to reduce the subluxation of nursemaid's elbow may result from improper reduction technique; swelling of the annular ligament as a result of edema, hemorrhage, or hematoma; or disruption of the annular ligament. Persistence of the subluxation also is more likely if reduction is attempted 12 hours or longer after the injury.

If two attempts at reduction fail to restore normal use of the arm, alternative diagnoses should be entertained. Because of the similarity in clinical findings, children also should be assessed for fractures of the clavicle and elbow. If no other pathologic process is found and the child is still not using the arm, a posterior splint should be applied with the elbow kept at 90 degrees and the forearm in supination. Follow-up evaluation with an orthopedic surgeon should be arranged for the next day.

Parents should be cautioned to avoid traction on the forearm and elbow because recurrence rates of radial head subluxation range from 5 to 39%, depending on the referral population studied.[20,22,24] With recurrent subluxations, immobilization in a posterior splint with the elbow maintained at 90 degrees and the forearm supinated may be warranted. The need for open reduction or repair of the annular ligament is exceedingly rare.

Toddler's Fracture

Toddler's fractures are oblique nondisplaced fractures caused by low-energy torsional forces applied to the porous bone of infants and young children. Previously, it referred only to tibial fractures in children between 9 and 36 months of age, but the term is now applied more loosely. The mechanism of injury can be as mild as the child's twisting on the leg while walking or a fall from an insignificant height. In some instances, the mechanism of injury may be unknown. The child will exhibit a limp or may refuse to walk on the affected leg. Some children will revert to crawling and can crawl without pain. Examination may show mild swelling of the leg and point tenderness. Gentle twisting of the lower part of the leg may elicit pain.

www.ketabpezeshki.com 66485457-66963820

Figure 176-19. Toddler's fracture.

AP and lateral radiographs may reveal a spiral or oblique fracture extending downward and medially through the distal third of the tibia (Fig. 176-19). An internal oblique radiograph is helpful if evidence of fracture is absent on the AP or lateral view. If findings on all views are normal, consideration should be given to fractures elsewhere in the limb. If no fracture is apparent, the child should be splinted for comfort and radiographs repeated in 10 days, at which time periosteal new bone or sclerosis of the fracture edges will make the fracture visible. If findings on these radiographs are normal and the child is still limping, further evaluation should be undertaken to rule out osteomyelitis and malignant neoplasm. Bone scans often are helpful in the assessment of a limping toddler and are more sensitive than plain radiographs for detection of fractures. Ultrasonography is also emerging as an imaging option in the detection of occult fractures in toddlers as well as in older children.[26] Treatment of a toddler's fracture consists of a below-knee walking cast for approximately 3 weeks.

The presence of a spiral fracture without an appropriate history may raise concern for nonaccidental trauma (i.e., child physical abuse). Midshaft fractures, which are more common in abused children, and tibial fractures in nonambulating children as well as other unexplained or frequent injuries should prompt further evaluation.

Skeletal Aspects of Nonaccidental Trauma

Perspective

Fractures are the second most common manifestation of child physical abuse, second only to soft tissue injury, and are present in up to 70% of physically abused children. Fractures associated with child abuse occur in the very young, 50% in children younger than 12 months[27] and 94% in children younger than 3 years.[28] With child abuse, a timely and accurate diagnosis is imperative because children who are returned to an abusive home face a 35% chance of repeated abuse and a 10% chance of death; more than 20% of children who were diagnosed with a fracture from nonaccidental trauma had at least one previous physician visit at which abuse was missed.[29]

No fracture is pathognomonic for abuse, but certain fracture patterns are more worrisome than others. Any fracture in a child younger than 1 year, fractures at different stages of healing, and bilateral or multiple fractures indicate a need for thorough assessment for nonaccidental trauma (see Chapter 66). Injuries that are especially concerning include complex skull fractures, rib fractures, metaphyseal fractures, and vertebral fractures or subluxations. Midshaft humeral and scapular fractures are nearly always associated with abuse, as are approximately 70% of femoral fractures in children younger than 1 year.

Specific Disorders and Injuries

Diaphyseal Fractures

Although multiple fractures at different stages of healing are strongly suggestive of child abuse, the most common manifestation is an isolated diaphyseal fracture, which occurs four times as often as classic metaphyseal fractures. The humerus, femur, and tibia are the most frequently fractured long bones; the radius and ulna are the most infrequently fractured. With the exception of supracondylar fractures, all fractures of the midshaft of the humerus in children younger than 3 years are strongly suggestive of abuse.

Metaphyseal Fractures

Although less common than diaphyseal fractures, metaphyseal fractures are more specific for child abuse. Metaphyseal fractures most commonly affect the tibia, femur, and proximal end of the humerus. Corner fractures and bucket-handle fractures, which are probably the same fracture viewed in two different projections, result from violent shaking or forceful pulling or twisting of an infant's limb. The diagnosis is made by careful evaluation of high-quality plain radiographs. The tight adherence of the periosteum at the metaphysis precludes an active periosteal response, making these fractures difficult to diagnose even in the healing stages. In addition, after healing, these fractures may not be visible because of rapid bone remodeling. Bone scans, although sometimes helpful, are difficult to interpret because of the normally increased radionuclide uptake in the metaphyseal area.

Rib Fractures

Rib fractures are present in 5 to 27% of cases of child abuse; 90% of such fractures occur in children younger than 2 years. The young pediatric rib cage is compliant, and considerable force is required to break a rib. Accordingly, rib fractures are seldom seen in unintentional injury and are almost never seen after cardiopulmonary resuscitation.[30] When present, postresuscitation rib fractures are anterior and also may be multiple.[30] In a child younger than 3 years, the positive predictive value of a rib fracture as an indicator of intentional trauma approaches 100%.[31]

With nonaccidental trauma, posterior rib fractures are most common and result from maximal mechanical stress as the rib is levered over the transverse process of the vertebral body when infants are grasped and shaken. The ribs fail mechanically at the head or neck. Abuse-related rib fractures tend to be multiple and symmetrical and may be difficult to diagnose acutely on standard radiographs. Repeated radiographic examination at 7 to 10 days after the injury is advised if findings on the initial films are normal but the level of clinical suspicion is high. Radiographic findings include callus formation or widening of the rib neck as a result of apposition of new bone subperiosteally. Bone scans can be helpful in detection of fractures in the acute setting.

Skull Fractures

Skull fractures are the second most frequent injury in abuse and occur more commonly in abuse cases than from unintentional trauma.[26] Eighty percent occur in infants younger than 1 year, and

www.ketabpezeshki.com 66485457-66963820

although complex skull fractures are more suspicious for abuse, linear skull fractures are the most common type. Standard skull radiographs may not be adequate for diagnosis and are reported to miss more than 25% of head injuries. Children who meet high-risk criteria (the presence of rib fractures, multiple fractures or facial injury, or age younger than 6 months) should undergo CT or MRI for assessment of occult head injury.[32]

Periosteal New Bone Formation

Periosteal new bone formation, which is one of the most common findings in cases of abuse, reflects separation of the periosteum from the bone and may be the only manifestation of orthopedic trauma related to child abuse. It may be present with or without a fracture. It results from shaking, from acceleration-deceleration forces applied to an unsupported limb, or from forceful gripping.

Diagnostic Strategies: Radiology. Conventional skeletal radiography is the screening examination of choice in cases of suspected physical abuse. Unsuspected fractures are found in 22% of physically abused children and are more common in the very young. A complete skeletal survey is recommended for all physically abused children younger than 3 years and for all infants younger than 1 year with evidence of abuse or neglect. Complete skeletal surveys are rarely indicated in children older than 5 years; in children between 3 and 5 years of age, the need for a skeletal survey is determined on a case-by-case basis. Although standard practice has been to obtain skeletal surveys in infants with skull fractures without intracranial injury or suspicious clinical findings, their routine use has come into question as they have been found to find additional fractures in only 1.4% of patients.[33]

A skeletal survey consists of an AP view of the extremities (including the hands and feet), frontal and lateral views of the thoracolumbar spine (including the ribs), and an AP and lateral skull series. In cases in which abuse is strongly suspected but radiographic findings are normal, bone scanning serves as an adjunct and is complementary to the skeletal survey in detection of injury. It is sensitive for detection of subtle rib, spine, and diaphyseal trauma, especially in the acute setting, but because the radiographic abnormalities can persist for years, it is not reliable in determination of the age of the fracture.

Differential Considerations. Although most cases of intentional injury are easily diagnosed with a thorough history and physical examination, certain conditions can be confused with child abuse. Metaphyseal cupping and spurring and periosteal new bone formation are two normal variants that radiographically are almost identical to the findings in cases of child abuse. These features are seen in more than 40% of normal infants. They appear between 2 and 3 months of age and may persist until 8 months of age. These findings can be differentiated from child abuse by subtle radiographic clues: normal-variant infantile metaphyseal spurs are in continuity with normal bone and cortex, and physiologic periostitis is bilateral, confined to the diaphysis, and smooth and lamellar in appearance. Physiologic periostitis also tends to be more obvious on the medial aspect of the bone and most commonly involves the femur, although it also is seen in the humerus and tibia. Radiographic differentiation between normal variants and trauma-related injury is extremely difficult, and the clinical findings must be taken into account.

Osteogenesis imperfecta (OI), a heritable disorder of connective tissue, is an alternative cause of multiple fractures with minimal trauma. In the United States, the estimated incidence is 1 in 20,000 persons. This estimate includes cases in children in whom the condition is diagnosed within 1 year of birth but does not include milder forms of the disease that are not diagnosed until later in life. Accordingly, the true incidence of OI may be significantly higher. Most types of OI have been linked to mutations in type I collagen genes that interfere with either the synthesis or the construction of collagen subunits. Clinical features include bone fragility, ligament laxity, defective dentinogenesis, short stature, scoliosis, middle ear deafness, blue sclera and tympanic membranes, and misshapen skull. On radiographs, the bones are diffusely osteopenic, with thin cortices and attenuated trabecular patterns. The long bones have narrow diaphyses, and bowing and fractures are common (Fig. 176-20).

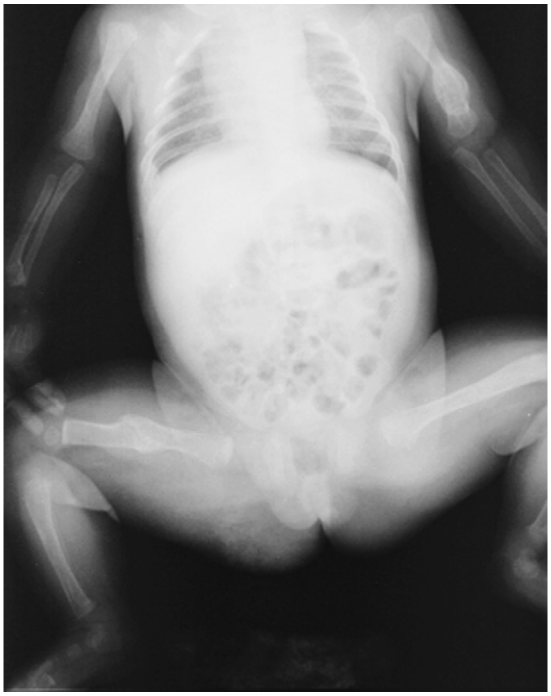

Figure 176-20. Radiograph obtained in a child with osteogenesis imperfecta. Note the narrow diaphyses, osteopenia, and multiple fractures.

Patients with OI present with a wide range of conditions from intrauterine demise to occurrence of multiple fractures in an infant to almost complete absence of symptoms in an adult. The diagnosis of OI is made on the basis of the history, physical examination, and radiographic findings. Confirmation is by skin biopsy and culture of dermal fibroblasts for evaluation of type I collagen. However, because the molecular basis for the entire spectrum of disease has not been established, up to 10% of cases of OI would be missed with skin biopsy alone. ED management of children with OI includes appropriate orthopedic referral for fractures and primary care referral for hearing evaluation.

In addition to musculoskeletal complaints, children with OI are predisposed to abdominal pain and neurologic abnormalities. The abdominal pain is thought to be related to the trefoil-shaped pelvis and acetabular protrusion associated with OI. These structural abnormalities narrow the pelvic outlet, resulting in partial rectosigmoid obstruction and subsequent constipation or obstipation. Neurologic abnormalities associated with OI result from basilar impression. Basilar impression, or elevation of the floor of the posterior cranial fossa, is reported to occur in 25% of patients with OI.[34] The signs of basilar impression (nystagmus, facial spasm, nerve paresis, pyramidal signs, and papilledema) may predate the symptoms (headache, neuralgia, imbalance, weakness, and incontinence). The most serious outcomes with basilar impression include brainstem compression, respiratory arrest, and sudden death. Any neurologic changes in a patient with OI mandate neurosurgical evaluation.

Several metabolic abnormalities can be associated with frequent fractures and radiographic abnormalities. Rickets, which results

www.ketabpezeshki.com 66485457-66963820

from vitamin D or calcium deficiency or hyperparathyroidism, can be manifested by diffuse osteopenia, fraying of the metaphysis, fractures, periosteal new bone formation, widening of the physis, and well-defined transverse stress fractures in the shafts of long bones. The diagnosis can be confirmed with laboratory testing. Menkes' kinky hair syndrome, a rare disorder of X-linked recessive inheritance involving inadequate copper absorption, is characterized by wormian (intersutural) skull bones, osteopenia, and metaphyseal fractures and spurring. Affected children have sparse, kinky hair with abnormal dentition and exhibit developmental delay. Serum levels of copper and ceruloplasmin are low and confirm the diagnosis. Hypervitaminosis A, although a rare cause of fractures, results in a thick periosteal reaction of tubular bones, most frequently the ulna and metatarsals, and widening of the cranial sutures. The epiphyses and metaphyses are normal. The diagnosis is based on the history and vitamin A levels.

Congenital syphilis also can mimic nonaccidental trauma. Skeletal findings in congenital syphilis frequently are diffuse and symmetrical and involve the long bones, skull, and small bones of the hands and feet. Radiographic findings include osteolytic defects, periosteal reaction, and metaphyseal lucencies parallel to the physis. The diagnosis is confirmed by serologic testing.

Developmental Dysplasia of the Hip

Perspective

Developmental dysplasia of the hip (DDH), formerly known as congenital dislocation of the hip, is abnormal formation of the hip joint that occurs between organogenesis and fetal maturity.[35] It encompasses a spectrum of disease ranging from "subluxatable" ("loose") hips to frank dislocation of the hips.

In white neonates, the incidence of dysplasia is 1%, and the incidence of dislocated hips is 0.1%. DDH is more common in Native American populations and less common in African American, Korean, and Chinese populations. An apparent familial predilection for the development of DDH has been reported; one British study noted that more than 20% of children who required treatment for DDH had a positive family history.[35] DDH is more common in girls and most frequently is unilateral (80%). With unilateral involvement, a predilection for the left side is characteristic. Associated birth factors include oligohydramnios, breech presentation, torticollis, talipes equinovarus, metatarsus adductus, and first-born status.[36] Postnatally, swaddling of infants with their hips and knees in extension predisposes to dislocation.

Principles of Disease

The etiology of DDH is not entirely clear. Three theories have been postulated: mechanical issues related to fetal position and environment, primary acetabular dysplasia, and ligamentous laxity that is enhanced by maternal relaxin hormone. Each theory has merit, and a combination of factors that contribute to the development of DDH is most likely.

Clinical Features

DDH may be diagnosed at birth, or despite frequent and appropriate physical examinations, it may not be discovered until later in life. In one study, 6% of children with documented DDH had normal findings on physical examination at birth.[35] Conversely, in more than 50% of infants found to have unstable hips at birth, spontaneous stabilization occurs within 3.5 days.[37]

The clinical manifestations of and physical examination findings with DDH are as diverse as the disease itself. This variability is due to differences in the severity of the dysplasia and the progressive changes that occur over time. Up to 4 to 6 months of age, the diagnosis of DDH is based on physical examination findings of leg length, skinfold, and range-of-motion asymmetry and abnormal findings on the Barlow provocative test and the Ortolani reduction maneuver. Skinfold asymmetry (Fig. 176-21) can be noted in the groin, below the buttock, and along the thighs. Although skinfold asymmetry is not specific for DDH, being present in approximately 30% of infants with normal hips, it is sensitive, and the diagnosis of DDH is unlikely in infants with normal skinfold symmetry. Range of hip motion also is helpful in diagnosis of DDH; any asymmetry in hip flexion, abduction, and external rotation should prompt further investigation. Although the general physical examination can be helpful in assessment of hip stability, the physical diagnostic cornerstones for diagnosis of DDH in young infants are the Ortolani reduction maneuver and the Barlow provocative test. The Ortolani reduction maneuver is performed in an attempt to reduce a dislocated hip into normal position, and the Barlow provocative test detects a subluxatable or dislocatable hip (Box 176-1). Abnormal findings are the presence of a clunk with the Ortolani test and any abnormal movement between the femoral head and the acetabulum with the Barlow maneuver.

After approximately 4 to 6 months of age, soft tissue contractures develop, the Ortolani and Barlow tests yield less information in detection of unstable hips, and range-of-motion abnormalities become more apparent. Parents may notice limited or asymmetrical leg movements or difficulty with diapering. Findings on examination include limited abduction (Fig. 176-22), relative shortening of the ipsilateral femur (Galeazzi's sign; Fig. 176-23), and skinfold asymmetry. In children with bilateral DDH, the diagnosis is even more difficult beyond the first few months of life because of the absence of asymmetry. After the development of contractures, physical findings in bilateral DDH include widening of the

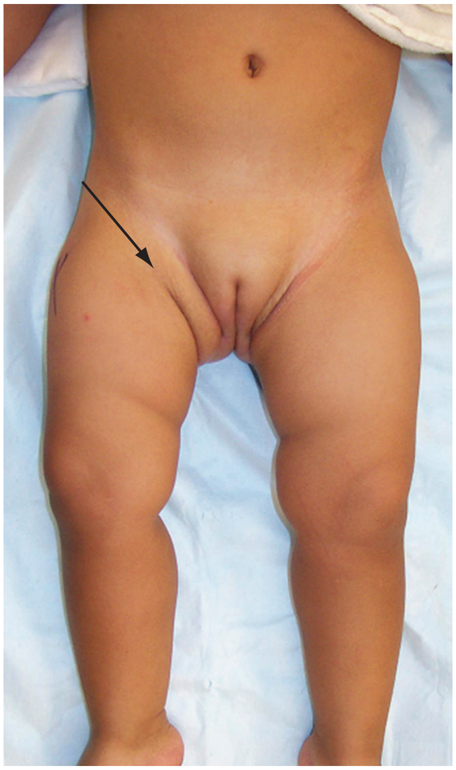

Figure 176-21. A 21-month-old child with right hip dislocation. Note the asymmetrical skinfolds in the upper thigh *(arrow)*. (From Storer SK, Skaggs DL: Developmental dysplasia of the hip. Am Fam Physician 74:1310, 2006.)

Box 176-1 Ortolani and Barlow Maneuvers

Ortolani (Reduction) Maneuver
1. Stabilize the pelvis with one hand.
2. With the other hand, slightly abduct the infant's hip.
3. With the index and long fingers over the greater trochanter, pull up the thigh to gently reduce the hip.

Barlow (Provocative) Test
1. Stabilize the pelvis with one hand.
2. Place the thumb on the inner aspect of the thigh near the lesser trochanter.
3. Adduct the hip.
4. Exert downward pressure on the thigh with the thumb and push it into the table.

Figure 176-22. A 3-year-old child with a left hip dislocation. Note the limited abduction. (From Storer SK, Skaggs DL: Developmental dysplasia of the hip. Am Fam Physician 74:1310, 2006.)

Figure 176-23. Galeazzi's sign in a 7-month-old girl with left hip dislocation. Apparent inequality of femur length is manifested as asymmetry in the level of the patient's knees. (From Storer SK, Skaggs DL: Developmental dysplasia of the hip. Am Fam Physician 74:1310, 2006.)

perineum, abduction of less than 60 degrees, and the appearance of abnormally short thigh segments.

With the onset of walking, gait asymmetry or asymmetrical in-toeing or out-toeing is a clue to the presence of DDH. Adduction and flexion contractures, Galeazzi's sign, hyperlordosis, and waddling gait are common features. Clinical observation of the appropriate maneuver reveals Trendelenburg's sign: while standing, the patient lifts one leg up at a time, and because the gluteal muscles are weakened on the affected side, the pelvis drops to the opposite side. With bilateral DDH, children have a wide-based waddling gait.

Diagnostic Strategies

Radiographs of infant hips are extremely difficult to interpret and may provide a false sense of security if the findings seem normal. Before the child is 3 to 6 months old, at which time the femoral head ossifies, an abnormal relationship between the upper end of the femur and the acetabulum may not be apparent. In addition, in infants with unstable but nondislocated hips, radiographs will show the hip in position, so its instability goes undetected. Before femoral head ossification, a better diagnostic test is ultrasonography.[38] Because a large percentage of infants will have abnormal ultrasound findings in the first week of life, with many of these abnormalities resolving within a few weeks,[35] it is best to delay ultrasound imaging in children with nondislocated but possibly unstable hips until 4 to 6 weeks of age. Children with dislocated hips require immediate ultrasound examination. Plain radiographs are useful after the age of approximately 6 months. A standard AP radiographic view of the pelvis with both legs extended in neutral abduction is then sufficient for diagnosis. Radiographic findings may include displacement of Shenton's line (a curvilinear line defined by the medial border of the femoral neck and the superior border of the obturator foramen) and a widened acetabular angle; angles greater than 30 degrees are abnormal, and those greater than 40 degrees indicate dislocation (Fig. 176-24).

Management

Treatment of DDH is most successful when it is begun early, and delay in detection can be associated with a significantly worse outcome. Patients with untreated abnormalities of the hips that persist beyond the newborn period are at risk for osteoarthritis, pain, abnormal gait, leg-length discrepancy, and decreased agility. For this reason, all children who are seen in the ED should have their hips examined until they are able to walk. Neonates who have a dislocated hip at birth should be referred to a pediatric orthopedist immediately. When a newborn has a loose but nondislocated hip, referral can be made within 2 weeks. Children with loose hips who are seen after the newborn period should be referred to a pediatric orthopedic surgeon immediately.

The essential basic goal of treatment is concentric reduction of the hip. After concentric reduction, stability should be obtained so that when the leg is allowed to move, it does not subluxate or dislocate. This position is maintained until all of the dysplastic features of the bone and cartilage have resolved. The two most important complications are failure to achieve these goals and aseptic necrosis of the femoral head.

In the first 6 months of life, use of the Pavlik harness is the mainstay of treatment. It is a dynamic splint that allows movement while preventing hip extension or adduction. Other treatment options include application of the Craig and von Rosen splints.[39] If these modalities are unsuccessful, application of a hip spica cast usually is the next choice. Beyond 6 months of age, use of a hip spica cast or fixed orthosis is required. Surgical release of contracted muscles may be necessary in older infants and children, and open surgical reduction is required if complete closed reduction is not achieved. Femoral or pelvic osteotomy (or both) may be necessary to reduce and to stabilize dislocated hips in children older than 18 months.[40] Beyond the age of 4 years in bilateral cases and 8 years in unilateral cases, reduction should not be attempted. The risk of aseptic necrosis and the potential for a poor result are too high.[36]

www.ketabpezeshki.com 66485457-66963820

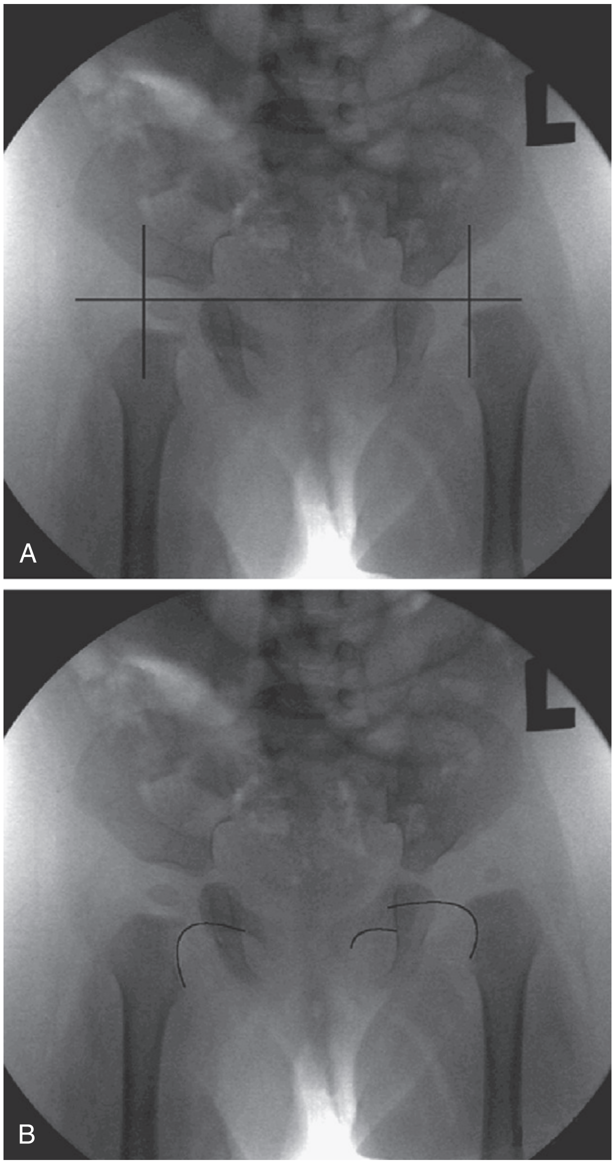

Figure 176-24. Anteroposterior radiographs obtained in a 7-month-old girl with developmental dysplasia of the left hip. **A,** The horizontal line is Hilgenreiner's line; the vertical lines are Perkin's lines. Note that the femoral head on the right (normal) side lies in the inferomedial quadrant formed by those lines. The left hip is dislocated; its femoral head lies in the superolateral quadrant. **B,** Shenton's line is disrupted on the left (dislocated) hip. Hip Pain in Children

Perspective

Hip pain in children is an extensive topic with myriad causes (Box 176-2). The extensive differential diagnosis precludes an in-depth review of the topic in this chapter, but an overview of some of the more common causes of hip pain in children is presented next.

Specific Disorders and Injuries

Transient Synovitis

Transient synovitis is the most common cause of hip pain in childhood.[41] It is a self-limited condition caused by a nonpyogenic inflammatory response of the synovium. Although it has been reported in children as young as 3 months and occasionally occurs in adults,[42] its peak incidence is between 3 and 6 years of age. Transient synovitis of the hip affects boys more commonly than girls and has a slight predilection for the right side. Less than 5% of cases are bilateral. Approximately half of the patients are seen acutely, usually within the first 3 days of the onset of symptoms, whereas the other half have a more insidious course, with symptoms occurring for weeks to months before medical evaluation.[43] Although transient synovitis most commonly affects the hip, it also can affect the knee.

The etiology of transient synovitis is unknown. Current theories imply an association with active or recent infection, trauma, or allergic hypersensitivity. At least half of the children with transient synovitis have or recently have had an upper respiratory illness.[44] One study demonstrated a fourfold rise in viral titers in 45% of patients and elevated serum interferon levels, consistent with a concurrent viral infection, in 43% of patients with transient synovitis.[45] Trauma commonly is associated with transient synovitis, but no clear relationship has been demonstrated. Similarly, a causal association with an allergic reaction to an infectious agent has been suggested but not proved.

It is estimated that transient synovitis of the hip may occur in up to 3% of children. Hip or groin pain is the most common initial finding, but referred pain to the medial aspect of the thigh or knee is found in 10 to 30% of patients. Affected patients either walk with a limp or, with severe pain, refuse to walk at all. The leg is held in flexion with slight abduction and external rotation. On examination, passive movement usually is pain free; however, pain and a slightly decreased range of motion may be noted with extreme internal rotation or abduction. Although most children with transient synovitis tend to otherwise be well, some will have a low-grade fever and malaise.

The diagnosis of transient synovitis is one of exclusion and relies on the history and physical examination in combination with limited laboratory testing and AP and frog-leg lateral radiographs of the pelvis. Laboratory tests are used to help distinguish children with transient synovitis from those with septic arthritis. In transient synovitis, laboratory values may be normal or may reveal mild elevations in the white blood cell count and erythrocyte sedimentation rate (ESR), both consistent with a nonspecific inflammatory process. Multiple studies have attempted to define criteria to help differentiate transient synovitis from septic arthritis. Clinical decision rules have included the presence or absence of fever, the ability to bear weight, white blood cell counts, the inflammatory markers ESR and C-reactive protein (CRP), side-to-side differences in the width of the joint space on radiographs, and previous visits to a health care provider for related symptoms. Kocher and colleagues found four independent multivariant predictors of septic arthritis: fever, inability to bear weight, ESR of

40 mm/hr or higher, and serum white blood cell count higher than 12,000 cells/μL. Patients with three of the four predictors had a 93% chance of having septic arthritis, and those with all four had a 99% likelihood.[46] A subsequent study to validate these findings showed that patients with none of the predictors had a 2% probability of septic arthritis; with one of four predictors, a 9.5% probability; with two of four predictors, a 35% probability; with three of four predictors, a 73% probability; and with all four predictors, a 93% probability of septic arthritis.[47] When this algorithm was tested at another institution, however, the presence of all four Kocher criteria predicted septic arthritis only 59% of the time.[48] In general, in children with transient synovitis and septic arthritis, the overlap of laboratory values and historical features is too great to provide a foolproof diagnostic algorithm.

Although radiographs of the hip and pelvis tend to be normal in appearance with transient synovitis, they are helpful to exclude other diseases. Radiographic findings consistent with transient synovitis include medial joint space widening, accentuated pericapsular shadow, and Waldenström's sign, which is lateral displacement of the femoral epiphysis with surface flattening secondary to effusion. However, these findings also are apparent in Legg-Calvé-Perthes disease and, if present, mandate close follow-up or further investigation with MRI. If joint aspiration is necessary to clarify the diagnosis, ultrasonography can be used to guide hip joint aspiration. Effusions are present in 60 to 70% of cases of transient synovitis; however, they also are present with septic arthritis, osteomyelitis, acute slipped capital femoral epiphysis (SCFE), Legg-Calvé-Perthes disease, rheumatoid and infectious arthritis, malignant disease, and osteoid osteoma. Accordingly, the presence of an effusion on ultrasonography cannot be used to distinguish transient synovitis from other causes of hip pain.[49] Nuclear scintigraphy in patients with transient synovitis is helpful in differentiation of transient synovitis from osteomyelitis (with or without septic arthritis), Legg-Calvé-Perthes disease, and SCFE. Scintigraphy may demonstrate differential uptake in the capital femoral epiphysis, with decreased uptake early in the course of the disease and increased uptake later on. The early changes also are seen with very early Legg-Calvé-Perthes disease and suggest that some children with transient synovitis experience ischemia of the capital femoral epiphyses. This ischemia may be caused by an intracapsular effusion that tamponades vessels along the femoral neck. These ischemic findings have not yet been shown to have clinical significance.

Most cases of transient synovitis can be managed at home with close follow-up by the child's primary care provider. In general, these children have a mild limp, and treatment with nonsteroidal anti-inflammatory medication often results in clinical improvement with relief of symptoms. A complete blood count and determination of ESR should be performed, and radiographs should be obtained. Patients with severe symptoms, fever, and elevated ESR should be evaluated for septic arthritis. If there is any doubt about the diagnosis, immediate orthopedic consultation is necessary.

Treatment of transient synovitis is twofold: (1) rest of the affected joint achieved with non-weightbearing or, in cases associated with extreme pain, bed rest and (2) reduction of the inflammatory process with anti-inflammatory medications. Temperatures should be monitored closely, and any fever should be reported to the physician. Children are allowed a gradual return to activity as the pain subsides, and full unrestricted activity is permitted when the hip is completely pain free with no evidence of a limp. Although many children with transient synovitis have an effusion, therapeutic aspiration of the joint is not routinely performed, and there is no strong evidence that aspiration shortens the clinical course or prevents osteonecrosis. Repeated examination is recommended for all children within 12 to 24 hours and then again after 10 to 14 days if the symptoms have not resolved.

The prognosis for children with transient synovitis is excellent. Up to 75% of patients have complete resolution of pain within 2 weeks and 88% within 4 weeks. The remainder may have less intense but persistent pain for up to 8 weeks. Relapse is possible, although infrequent, and usually occurs within 6 months. In general, long-term sequelae of transient synovitis are infrequent; these may include asymptomatic coxa magna (enlargement and deformity of the femoral head and neck caused by hypertrophy of cartilage secondary to inflammation) and mild degenerative cystic changes of the femoral neck. These changes persist for years and may be accompanied by radiographic degenerative change, but they do not tend to cause long-term functional disability. In addition, a small number (2%) of cases of transient synovitis follow a clinical and radiographic course consistent with Legg-Calvé-Perthes disease. Whether this is due to ischemia of the capital femoral epiphyses during the early stages of synovitis or reflects an initial misdiagnosis is unclear. It is recommended that children with persistent symptoms undergo ultrasonography to evaluate for the presence of an effusion. Persistent joint effusion beyond 4 to 6 weeks may be associated with the subsequent development of Legg-Calvé-Perthes disease.[50] Some experts recommend routine 6-month follow-up radiographs for all children with transient synovitis,[43] whereas others reserve radiographs for children who remain symptomatic.[51]

Acute Septic Arthritis

Septic arthritis refers to microbial invasion and infection of the joint space. Bacterial pathogens are common in patients with acute septic arthritis, whereas fungal and mycobacterial pathogens tend to be associated with a more indolent septic arthritis. Acute septic arthritis occurs in all age groups but is more common in children; 70% of cases occur in children younger than 4 years, and the peak incidence is between 6 and 24 months. Boys are affected twice as frequently as girls. Predisposing factors include preceding viral infection, trauma, immunodeficiency, hemoglobinopathy, hemophilia with recurrent hemarthroses, diabetes, injection drug abuse, rheumatoid arthritis, and intra-articular injections or operations. In 75% of cases of septic arthritis, the pathologic process involves the joints of the lower extremity, with the knee being most commonly and the hip second most commonly involved. Other affected joints, in order of involvement, include the ankle, elbow, shoulder, and wrist. More than 90% of the cases are monarticular.

Hematogenous seeding, local spread, or traumatic or surgical infection may cause septic arthritis. In children, it most commonly results from hematogenous spread as bacteria pass into the synovial space through the highly vascular synovial membrane. The synovial membrane lacks a limiting basement membrane, which facilitates bacterial translocation. The bacteria then bind to bone and cartilage, initiating an inflammatory response that breaks down the joint by two mechanisms: directly through the effects of proteolytic enzymes and indirectly through pressure necrosis caused by accumulation of purulent synovial fluid.

Contiguous spread of infection from osteomyelitis to the joint space occurs in approximately 10% of cases and is more common in newborns and young infants. In these children, blood vessels cross the physis, thereby connecting the metaphysis and epiphysis and allowing bacteria direct access into the joint space. In addition, the joint capsules of the hip and shoulder overlie the bony metaphyses of the femur and humerus, facilitating direct extension of osteomyelitis into these joint spaces.

The most common bacterial causes of septic arthritis are listed in Table 176-5. Overall, *Staphylococcus aureus* is the most common cause of septic arthritis and infection in children; community-acquired methicillin-resistant *S. aureus* (MRSA) accounts for up to 65% of *S. aureus* infections.[52] In neonates, group B streptococci and gram-negative organisms are common causes. In addition to

www.ketabpezeshki.com 66485457-66963820

the organisms listed in Table 176-5, additional causative organisms include *Neisseria gonorrhoeae* in neonates and sexually active adolescents, *Pseudomonas aeruginosa* and *Candida* species in injection drug abusers, *Salmonella* species in children with sickle cell disease, and gram-negative bacteria in immunosuppressed children. *Kingella kingae,* a fastidious gram-negative coccobacillus that colonizes the respiratory and oropharyngeal tracts in children, has been implicated as a common cause of osteoarticular infections in young children. *K. kingae* was found to be the causative agent in up to 50% of osteoarticular infections.[53,54] In previously well children, more than 95% of *K. kingae* infections are diagnosed between 6 months and 4 years of age; it may also cause infections in older children with underlying medical conditions.[55] Fortunately, *K. kingae* is susceptible to a wide array of antibiotics that are given empirically to young children for septic arthritis.

The clinical picture of septic arthritis varies with age. Infants tend to have fever, failure to feed, lethargy, pseudoparalysis of the extremity, and pain with being handled. In one study, however, neonates (younger than 1 month) were found to have less fever and fewer systemic signs of illness than in older infants, thus making the diagnosis even more difficult. Most older children have systemic signs and symptoms of fever, malaise, poor appetite, and irritability as well as localized symptoms of pain and refusal to move the affected joint or, if the lower part of the body is involved, limp or refusal to walk. With septic arthritis, the onset of symptoms is more acute than with osteomyelitis. Physical examination reveals local erythema, warmth, and swelling. If the hip is affected, it often is held in flexion, abduction, and external rotation. Range of motion is decreased because of pain and muscle spasm, and passive joint movement is painful. In infants, joint dislocation may be observed.

Table 176-5 Septic Arthritis Pathogens and Treatment

AGE	ORGANISM	TREATMENT
Birth to 2 months	Group B streptococci *Staphylococcus aureus* Gram-negative rods *Neisseria gonorrhoeae*	Nafcillin, 50 mg/kg, and cefotaxime, 50-75 mg/kg
2 months to 5 years	*Staphylococcus aureus* *Streptococcus pneumoniae* *Streptococcus pyogenes* *Kingella kingae* *Haemophilus influenzae*	Nafcillin, 50 mg/kg, and ceftriaxone, 50 mg/kg (consider vancomycin, 10 mg/kg)
5 years to 12 years	*Staphylococcus aureus* *Streptococcus pyogenes*	Nafcillin, 50 mg/kg, and ceftriaxone, 50 mg/kg (consider vancomycin, 10 mg/kg)
>12 years	*Staphylococcus aureus* *Neisseria gonorrhoeae*	Nafcillin, 50 mg/kg, and ceftriaxone, 50 mg/kg (consider vancomycin, 10 mg/kg)

Laboratory studies helpful in diagnosis of septic arthritis include a white blood cell count, ESR, CRP assay, blood cultures, and evaluation of joint fluid. Use of the white blood cell count and ESR is discussed in the section on transient synovitis. The ESR rises 24 hours or more after the onset of signs and symptoms of infection, so it may not be helpful during the first day of illness. The CRP level may be a better monitor than the ESR for septic arthritis. The CRP assay is a simpler test that requires only a fingerstick sample of blood. The CRP level rises more quickly than the ESR, typically is elevated at the time of the initial evaluation, and with appropriate therapy will normalize within a week; by contrast, the ESR will not normalize for more than a month.[56] In patients with septic arthritis, the peripheral white blood cell count, ESR, and CRP level generally are elevated, although white blood cell counts and acute-phase reactants may be normal, especially with *K. kingae* infection.[55,57]

Blood cultures should be included in the evaluation of a child with suspected septic arthritis. Culture results are positive in 20 to 50% of cases.[56] When culture results are positive, they not only help direct antibiotic treatment but also provide an organism for serum bactericidal testing as the child progresses to oral antibiotics.

If *N. gonorrhoeae* infection is suspected, special media are required for cultures of joint fluid, blood, pharynx, skin lesions, cervix, urethra, vagina, and rectum. Urine, urethral, cervical, and vaginal specimens also can be obtained for nucleic amplification testing.

If the patient has signs or symptoms of pharyngitis, a throat swab should be sent for culture of *Streptococcus pyogenes*. Antibody titers to antistreptolysin O and anti-DNase B also may help in establishment of a causative organism.

Evaluation of synovial fluid is the standard modality for diagnosis of septic arthritis. If septic arthritis is being considered, joint aspiration should be performed without delay and the sample sent for Gram's stain, aerobic and anaerobic cultures, cell count with differential count, and glucose determination. The synovial fluid in patients with septic arthritis tends to be turbid or grossly purulent, with a white blood cell count higher than 40,000 cells/μL and a predominance of polymorphonuclear cells (Table 176-6). Synovial glucose concentration may be low (synovial fluid glucose/blood glucose ratio of less than 0.5) and protein and lactate levels elevated. Because of the intrinsic immunoglobulins in the synovial fluid, results on culture of the fluid will be positive in only half of the children in whom the clinical picture is consistent with septic arthritis. Joint fluid should be inoculated directly into blood culture bottles to enhance identification of fastidious organisms such as *K. kingae*.[52,57] Culture specimens may need to be incubated for a week or longer.[54]

In septic arthritis of the hip, plain radiographs may be normal in appearance or, in the presence of a large joint effusion, may

show periarticular soft tissue swelling, widening of the joint space, obliteration or displacement of the gluteal lines, and asymmetrical fullness of the iliopsoas and obturator soft tissue planes. Late in the course of infection, subchondral bone erosions and narrowing of the joint space are seen. Ultrasonography is much more sensitive than plain radiography for detection of hip effusion and provides direct visualization of the fluid and needle during joint aspiration. Scintigraphy also may be useful in diagnosis of septic arthritis; during the "blood pool" or delayed images of the joint, symmetrical uptake in periarticular tissue on both sides of the joint is seen. Scintigraphy is diagnostic of septic arthritis earlier than other imaging techniques are and is a useful adjunct in identification of associated osteomyelitis or avascular necrosis of the femoral head. CT can confirm the presence of an effusion but does not differentiate septic from nonseptic arthritis. Changes in signal intensity and femoral epiphysis perfusion seen on MRI may provide diagnostic clues in attempting to differentiate septic arthritis from transient synovitis.[58,59]

Septic arthritis requires immediate hospital admission, antibiotics, and surgical intervention. Surgical options range from needle aspiration to open surgical drainage, but no randomized, controlled trials have compared these two treatment approaches. Some experts recommend surgical drainage in all infants and young children with septic arthritis because needle aspiration has been shown to be inferior in this population.[60] Indications for surgical drainage in children with septic arthritis include involvement of the hip joint, presence of large amounts of pus or debris in the joint, loculated fluid, recurrence of joint fluid after four or five aspirations, and lack of clinical improvement within 3 days of the initiation of appropriate therapy.[61-64] In joints other than the hip, the need for surgical drainage is determined on a case-by-case basis.

Empirical antibiotic therapy for septic arthritis is directed against the most likely organisms as dictated by the patient's age and comorbid conditions (see Table 176-5). Treatment may then be changed after culture and sensitivity results are known. If a pathogen is not isolated but the patient is improving, initial antibiotic therapy is continued. If a pathogen is not identified and the patient is not improving, reaspiration of the joint or the possibility of a noninfectious process should be considered. To maximize culture results, antibiotics should not be given until a specimen of joint fluid is obtained. Initial treatment should be parenteral to ensure adequate serum antibiotic concentrations. In neonates, the entire course of antibiotics should be administered parenterally. Patients older than 1 month can be transitioned to oral antibiotics after they have been afebrile for 48 to 72 hours and have improved signs and symptoms of infection, a white blood cell count that has normalized, and decreasing inflammatory markers (CRP and ESR). In general, doses two to three times those used for mild infections are sufficient. Response to therapy is measured by clinical improvement and assays for acute-phase reactants (CRP and ESR).

The mortality rate associated with septic arthritis has fallen to less than 1%, but the morbidity remains significant. Sequelae include leg-length discrepancy, persistent pain, limited range of motion and ambulation, and ischemic necrosis of the femoral head. Predictors of a poor outcome include infection of the hip or shoulder, adjacent osteomyelitis, delay of 4 days or more before antibiotic and surgical intervention, and prolonged time to sterilization of synovial fluid.

Legg-Calvé-Perthes Disease

Idiopathic avascular necrosis of the proximal femoral epiphysis, also known as Legg-Calvé-Perthes disease, is named after the men who independently described it in the early 1900s. It usually occurs between the ages of 3 and 12 years, with the peak incidence between the ages of 5 and 7 years. Legg-Calvé-Perthes disease has been reported in teenagers as well as in children as young as 2 years. Boys are affected three to five times more frequently than girls, and the disease is familial approximately 10% of the time. The disorder is bilateral in up to 20% of cases. Trauma often is related to the onset of symptoms, but a direct relationship between the two has not been clearly established. Thrombophilia also may be associated with Legg-Calvé-Perthes disease; however, studies are conflicting.

Despite extensive research, the etiology of Legg-Calvé-Perthes disease remains unclear. Ponseti and colleagues[65] suggested that the disease is a local manifestation of a transient generalized disorder of epiphyseal cartilage. Their histologic studies showed thickening and disorganization of the growth plate, which could block penetration of the blood vessels and render the femoral epiphysis avascular. Other etiologic theories involve abnormalities in the vascular anastomotic network around the femoral epiphysis, increased blood viscosity leading to infarction, and abnormalities in growth hormone.

On clinical examination, children with Legg-Calvé-Perthes disease initially exhibit a limp of insidious and stuttering onset. Associated pain, when present, usually is related to activity and relieved by rest. The pain tends to be localized to the groin or referred to the anteromedial aspect of the thigh or knee region. Symptoms and limp severity usually are worse at the end of the day. On examination, children have limited hip motion, particularly abduction and internal rotation. Early in the course of disease, the limited abduction is secondary to synovitis and muscle spasm. As the disease progresses, limitation of motion is due to deformity of the femoral head, and with time, the limited abduction may become permanent. Children with Legg-Calvé-Perthes disease demonstrate Trendelenburg's sign (see the earlier section on developmental dysplasia of the hip) accompanied by thigh, calf, and buttock atrophy related to disuse. With advanced disease and femoral head collapse, limb-length discrepancy may be noted.

The role of laboratory evaluation in the diagnosis of Legg-Calvé-Perthes disease is limited to ruling out of other causes of hip pain (e.g., septic arthritis) when the diagnosis is in question or evaluation for hormonal, metabolic, or genetic causes in patients with bilateral hip involvement.

Legg-Calvé-Perthes disease is diagnosed and staged by plain radiographs obtained in the AP and frog-leg lateral views. This radiographic survey shows the extent of epiphyseal involvement and the stage of the disease and also provides prognostic information. Radiographic "head at risk" signs that are associated with poor results include a radiolucent V-shaped defect in the lateral epiphysis and adjacent metaphysis (Gage's sign), speckled calcification lateral to the capital epiphysis, diffuse metaphyseal reaction (metaphyseal cysts), lateral capital femoral epiphysis subluxation, and horizontal physis. These prognostic signs help guide treatment. In early Legg-Calvé-Perthes disease, radionuclide bone scanning may be diagnostic before the development of abnormalities on plain film. Bone scintigraphy also has been shown to provide accurate information concerning the extent of the necrotic process as well as the degree of vascularization and hence the stage of the disease. Scintigraphy, however, was not able to predict disease outcome.[66] Compared with plain radiography and bone scanning, MRI gives earlier and more reliable information about the extent of necrosis of the femoral head. MRI also is better than scintigraphy at showing revascularization. Despite the usefulness of MRI in early Legg-Calvé-Perthes disease, its role in healed Legg-Calvé-Perthes disease is limited because it provides no additional information about the configuration and structure of the femoral head beyond that from plain radiography.[66] Arthrography is useful in delineation of flattening of the femoral head, demonstration of the hinge abduction phenomenon with abduction of the leg, and, in conjunction with plain films or CT, diagnosis of osteochondritis dissecans after Legg-Calvé-Perthes disease.

www.ketabpezeshki.com 66485457-66963820

Figure 176-25. Crescent sign (subchondral lucent zone) in early Legg-Calvé-Perthes disease. (Courtesy Marianne Gausche-Hill, MD.)

There are four radiographic classification stages of Legg-Calvé-Perthes disease: initial, fragmentation, reossification, and healed. Radiographic findings in the initial stage include a femoral head that appears smaller than the opposite unaffected femoral head, widening of the medial joint space, subchondral lucent zone (subchondral collapse, the so-called crescent sign; Fig. 176-25), irregular physeal plate, and blurry and radiolucent metaphysis. In the fragmentation phase, the repair aspects of the disease become more prominent. The epiphysis begins to fragment, and areas of increased radiolucency appear as new bone forms as well as areas of increased radiodensity. During the reossification stage, the repair process continues as normal bone density returns, radiodensities replace radiolucencies, and alterations in the shape of the femoral head and neck become apparent. The healed stage is the final radiographic stage of Legg-Calvé-Perthes disease, and radiographs of the proximal third of the femur obtained during this stage of the illness will demonstrate any residual deformities.

Multiple prognostic classification systems of Legg-Calvé-Perthes disease have been devised. In general, a poor prognosis is associated with a greater degree of deformity of the femoral head and acetabulum at maturity, disease onset in children 6 to 8 years of age or older, female gender, and prolonged duration of disease.

When the diagnosis of Legg-Calvé-Perthes disease is suspected, orthopedic consultation is recommended. Goals in the treatment of Legg-Calvé-Perthes disease are to improve range of motion, to prevent deformity, to limit growth disturbance, and to prevent degenerative joint disease. Treatment is not indicated in all affected children, but when it is indicated, it should be started in the initial or fragmentation phase of the disease. Treatment is recommended for patients who have a poor prognosis on the basis of clinical and radiographic findings. The cornerstone for treatment of Legg-Calvé-Perthes disease is referred to as containment: the femoral head is contained within the acetabulum to equalize pressure on the head and to subject it to the molding action of the acetabulum to maintain the spherical nature of the femoral head. Containment can be achieved through nonoperative or operative methods, and optimal treatment is determined on a case-by-case basis.

Residual deformities resulting from Legg-Calvé-Perthes disease follow four patterns: coxa magna (enlargement and deformation of the head of the femur), premature physeal arrest, irregular head formation, and osteochondritis dissecans. Despite these deformities, most patients with childhood hip disease are capable of bone remodeling with subsequent improvement in femoral head deformities. During their early years, regardless of radiographic appearance, patients with Legg-Calvé-Perthes disease tend to do well.[67] A majority (70-90%) of patients are active and pain free and have good range of motion 20 to 40 years after the onset of symptoms. Only patients with flattened irregular femoral heads at the time of primary healing or premature physeal closure experienced clinical deterioration and increasing pain.[68] Later in life, function becomes markedly reduced, and degenerative joint disease develops in a majority of patients by their 50s and 60s.[67] With noncontainment treatment, however, the outcome is not as good. Yrjonen found that at an average of 35 years of follow-up, 48% of patients had evidence of degenerative joint disease and 17% either had undergone total hip arthroplasty or had clinical symptoms that warranted total hip arthroplasty.[69]

Slipped Capital Femoral Epiphysis

SCFE refers to posterior and inferior slippage of the proximal femoral epiphysis on the metaphysis. The femoral head sits securely in the acetabulum, whereas the epiphysis separates from the femoral neck through the growth plate. The average annual incidence of SCFE ranges from 0.2 (in Japan)[70] to 10.8 (in the United States) per 100,000 children; boys are affected almost twice as frequently as girls are.[71] The peak incidence is during the adolescent growth spurt: boys between 12 and 16 years of age (mean age, 13.5 years) and girls between 10 and 14 years of age (mean age, 11.5 years). The age at diagnosis decreases with increasing obesity. A majority of children with SCFE have delayed skeletal maturation, with bone age being as much as 20 months behind chronologic age. African American and Hispanic children are affected more frequently than white children are. The literature reports SCFE to be bilateral in up to 80% of cases, although 30 to 40% of these cases are asymptomatic and discovered only on screening radiographs. In unilateral cases, the left hip is affected twice as often as the right.

SCFE is associated with endocrine disorders (hypothyroidism, panhypopituitarism, hypogonadism, and growth hormone administration), renal osteodystrophy, and radiation therapy. Most cases of SCFE, however, are idiopathic and associated with obesity. The etiology of idiopathic SCFE is unknown. It is likely to be multifactorial and related to biomechanical factors such as obesity and physeal architecture as well as hormonal factors that weaken physeal strength. Obesity results in increased shear forces across a more vertically and posteriorly oriented growth plate that has been weakened by architectural irregularities and hormonal changes of puberty. The consequence is slippage of the epiphysis inferiorly and posteriorly in the direction of the weight-bearing force.

The traditional classification of SCFE was based on the duration of symptoms, with acute slippage defined as symptom duration of less than 3 weeks, chronic slippage defined as symptoms for 3 weeks or longer, and acute-on-chronic slippage defined as symptom duration of more than 3 weeks with a recent sudden exacerbation. This classification has been replaced by one based on stability: in stable SCFE, ambulation is possible (with or without crutches), whereas in unstable SCFE, ambulation is not possible (with or without crutches).[72] This classification system is preferred to the traditional classification because it does not rely on patient or parent recall for duration of symptoms and provides information about prognosis.

The signs and symptoms of SCFE vary with its stability. Children with stable SCFE have symptoms of intermittent limp and pain of several weeks to months in duration. Stable SCFE is found in approximately 95% of all cases.[72] The pain of SCFE may be localized to the hip but more commonly is poorly localized to the thigh, groin, or knee. Atypical manifestations of SCFE include weakness and easy fatigability of the affected limb and limping on exertion. With continued slippage, internal rotation, flexion, and abduction are lost, and parents and children may note progressive external rotation and shortening of the involved lower extremity with subsequent difficulty in daily activities, such as tying shoes. On examination, children initially have a slight loss of internal rotation and experience pain only at the extremes of motion. Their

www.ketabpezeshki.com 66485457-66963820

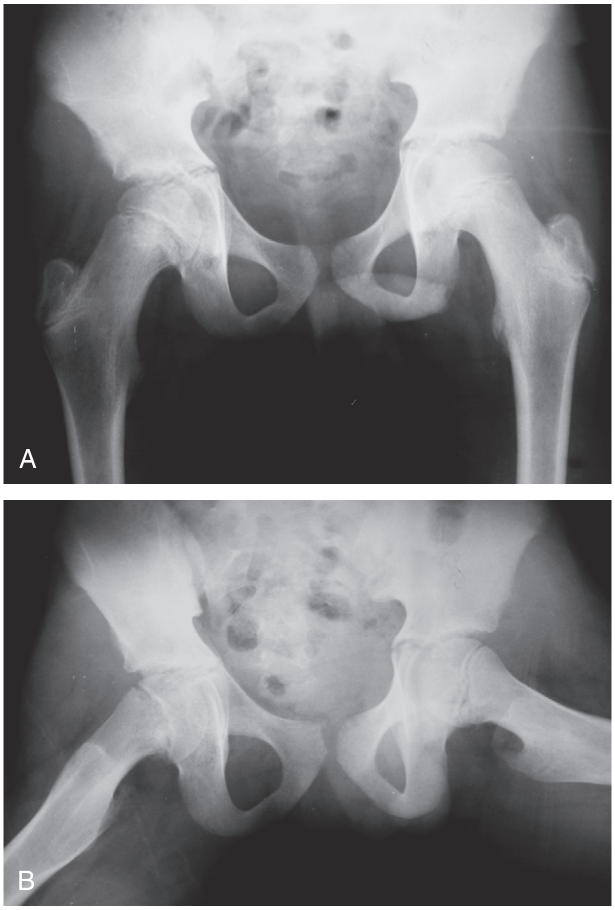

Figure 176-26. A, Anteroposterior radiograph of the pelvis with a unilateral slipped capital femoral epiphysis; note widening of the physis on the right compared with the left. B, Early inferior and posterior slippage is evident on the lateral view. (A and B courtesy Marianne Gausche-Hill, MD.)

gait is antalgic, and muscle atrophy is minimal. As the slip becomes more severe, the gait becomes more antalgic, internal rotation is lost, abduction and flexion of the hip increase, thigh and gluteal muscle atrophy is more pronounced, and leg-length discrepancy develops. A frequently seen sign associated with SCFE can be elicited during passive flexion of the affected hip: as flexion is increased from an extended position, the thigh abducts and externally rotates.

Unstable SCFE in children typically initially comes to attention after a sports-related injury or a fall with a twisting injury. These children experience acute onset of extreme pain and, on examination, hold the hip in flexion, external rotation, and abduction. The children resist any type of movement of the affected leg, and if unstable SCFE is suspected, no passive movement should be attempted for fear of further displacement of the epiphysis.

The diagnosis of SCFE is made with AP and lateral radiographs of both hips. With stable slippage, AP and frog-leg lateral pelvic radiographs should be obtained. When an unstable slip or a minimal slip is suspected, a cross-table radiograph replaces the frog-leg lateral view. Early in the course of SCFE, the initial slippage is posterior, so the AP view is normal in appearance or shows widening of the physis; the slip is better seen on the lateral projection (Fig. 176-26). Early findings on lateral radiographs include a minimal posterior step-off at the anterior physeal plate and widening of the growth plate. On AP radiographs, signs of slippage include Klein's line and the blanch sign of Steele. Klein's line is a line drawn along the superior margin of the femoral neck. With a normal hip, the line intersects with or falls within the epiphysis, whereas in a hip with a slipped epiphysis, the line does not come in contact with the epiphysis. The blanch sign of Steele is a crescent-shaped area of increased density in the proximal portion of the femoral neck that is created by superimposition of the posteriorly displaced epiphysis on the femoral neck. The femoral metaphysis of the affected hip also appears to be more laterally displaced from the medial wall of the acetabulum. As the slip continues, the epiphysis continues to be displaced inferiorly and posteriorly relative to the metaphysis. Over time, remodeling smoothes away the superior and anterior portions of the femoral neck, and in an attempt to buttress the slippage, callus is formed at the inferior and posterior portions of the femoral neck. Acute, unstable slips in children without previous symptoms will not be associated with evidence of bone healing or remodeling.

Ultrasonography has been used in the diagnosis of SCFE but offers little if any information beyond that provided by conventional radiography. CT and MRI can be used to confirm and to quantitate epiphyseal displacement in patients who have symptoms but no radiographic findings suggestive of SCFE.

Slip severity is described in either of two ways. The simplest classification describes the amount of displacement of the femoral head on the femoral neck. In mild SCFE, the amount of displacement is less than one third; moderate SCFE has displacement between one third and one half; and severe SCFE is marked by displacement of the femoral head by more than half the width of the femoral neck. A more accurate description of the magnitude of slippage is obtained by measurement of the epiphyseal-shaft angle of Southwick. On a frog-leg lateral radiograph of the pelvis, a line is drawn between the anterior and posterior tips of the epiphysis at the physeal plate level. A second line is then drawn perpendicular to the epiphyseal line. Next, a line is drawn along the midshaft of the femur. The epiphyseal-shaft angle is formed by the intersection of the perpendicular and the femoral shaft lines. The magnitude of slip displacement is the angle of the involved hip minus the angle of the normal hip. If involvement is bilateral, 12 degrees is used as the control angle. Mild SCFE involves displacement of less than 30 degrees, a moderate slip is between 30 and 50 degrees, and severe displacement is more than 50 degrees.[73]

When SCFE is diagnosed in the ED, non-weightbearing status is assigned immediately, and the child is provided with either crutches or a wheelchair; an urgent orthopedic consultation should be obtained. For a stable slip, definitive treatment is best performed within a few days; however, hospital admission is prudent. With an unstable slip, some orthopedic surgeons recommend immediate fixation.

The goals of treatment are to prevent further slippage and to achieve physeal stability, to avoid complications, and to maintain adequate hip function. A stable slip can be fixed with internal fixation (pinning), bone graft epiphyseodesis, corrective osteotomy, or spica cast immobilization. Most orthopedic surgeons recommend internal fixation with a single central screw. Failure of this repair is rare, and with new techniques that avoid opening of the hip joint, it has become a procedure associated with minimal blood loss and wound complications and minimal need for hospitalization and rehabilitation. Postoperatively, non-weightbearing or touch-toe weightbearing for 4 to 6 weeks is followed by a gradual return to normal activity. Running and contact sports may be resumed once the physis is closed. With unstable SCFE, controversy has arisen about the timing of the surgery, the optimal number of fixative devices that should be used, whether reduction should be performed, and whether preliminary traction and bed rest should be used before surgery. Treatment is dependent on the degree of slippage and the preference and experience of the orthopedic surgeon.

The two most worrisome short-term complications of SCFE are avascular necrosis and chondrolysis; the risk for either process

www.ketabpezeshki.com 66485457-66963820

increases with the severity of the initial slippage.[74] Avascular necrosis has been reported to occur in 10 to 15% of children with SCFE. The risk is higher with unstable SCFE,[75,76] greater degrees of slippage, and multiple attempts at reduction.[76] In children with stable slips treated by single-screw internal fixation without reduction, reported rates of avascular necrosis are as low as 0 to 5%.[77]

Chondrolysis occurs in approximately 5% of patients with SCFE, with an increased incidence in children with greater degrees of slippage. Chondrolysis may develop before and as a result of treatment. It should be suspected when pain and loss of motion are disproportionate to the severity of the slip. On radiographs, loss of articular cartilage may be seen. When SCFE is treated by spica cast immobilization, the rate of chondrolysis is reported to range from 19 to 67%.[78,79] Approximately 50% of cases of chondrolysis will resolve during the course of several years; however, in other cases, it may progress to such severe pain and contractures that hip arthrodesis is needed.

Other complications of SCFE include nonunion, premature closure of the epiphyseal plate, and degenerative changes. Degenerative hip arthritis develops gradually during decades and has an earlier onset with more severe degrees of slippage.

Apophyseal Injuries

Perspective and Principles of Disease

The apophysis is a cartilaginous structure that serves as a site for insertion of tendons on the growing bone. It has its own growth plate that has a slower rate of growth than the nearby epiphyseal plate. Apophysitis is unique to patients with skeletal immaturity and involves inflammation of this actively growing bone prominence that is under great tensile stress. Common apophyseal injuries include medial epicondylitis, Osgood-Schlatter syndrome, and Sever's disease.

Apophysitis may be secondary to a single episode of macrotrauma or may follow repetitive microtrauma to the secondary center of ossification, which causes multiple tiny avulsion fractures. This scenario sets up an inflammatory cycle that is perpetuated by continued activity and trauma to the apophysis.

Growth also contributes to the development of apophysitis. As the musculoskeletal system goes through a growth spurt, muscle development lags behind bone development. This difference in development leads to a muscle-tendon imbalance manifested as tight and inflexible muscle groups in which excessive stress is placed on the apophyseal centers at which these muscles insert.

The true incidence of apophysitis is unknown. One study found an incidence of 18% in a population of 1000 patients seen at an urban general pediatric clinic during a 4.5-month period.[80] Another study, which looked at patient visits to a sports medicine clinic, found an incidence of 31%.[81] Children between 8 and 15 years of age most frequently are affected, with involvement of different apophyseal centers affected at different ages.

Specific Disorders and Injuries

Osgood-Schlatter Syndrome

In 1903, Osgood and Schlatter independently reported traumatically induced apophyseal injury to the tibial tubercle in adolescents.[82] This entity, now known as Osgood-Schlatter syndrome, is the most common of the apophyseal disorders.[83] It is found most commonly in boys between 10 and 15 years of age and in girls between 8 and 13 years of age and frequently is bilateral. Boys are affected more often than girls are, although this trend is changing as more girls are becoming increasingly involved in competitive sports. Bilateral involvement is found in 20 to 30% of patients.

Clinically, patients with Osgood-Schlatter syndrome have tenderness, pain, and swelling at the site of insertion of the patellar tendon on the tibial tubercle. The tibial tubercle may be prominent and the quadriceps tight. Pain is worsened with activities (such as running and jumping) that cause the quadriceps to contract, thereby stressing the tubercle. Extension of the knee against resistance causes pain, but resisted straight-leg raises are painless. Osgood-Schlatter syndrome is a clinical diagnosis, and radiographs generally are not indicated. If radiographs are obtained, however, lateral views of the tibial tubercle may appear normal or may show an enlarged, fragmented, and irregular tibial tuberosity with or without an overlying bony ossicle. These findings are nonspecific, however, and are not diagnostic on their own. Ultrasonography, which has been proposed as a diagnostic tool by some experts, may reveal pretibial swelling, fragmentation of the ossification center, insertional thickening of the patellar tendon, or excessive fluid collection in the infrapatellar bursa.[84]

Treatment of Osgood-Schlatter syndrome is conservative and symptomatic. Initially, the pain can be effectively managed with ice and modification of activity, with or without nonsteroidal anti-inflammatory medications. The use of a patellar strap may help relieve symptoms. After the acute inflammatory process has resolved, treatment focuses on strengthening and stretching of the quadriceps muscles. Mild pain during activity is not an absolute contraindication to participation; however, with more severe symptoms, the risk of avulsion of the tibial tubercle should be weighed against the benefits of competing. In rare instances, conservative therapy is insufficient, and a 2- to 3-week trial of crutches is required. Steroid injections have been used in the past but are not currently recommended owing to the associated risk of patellar tendon rupture. Complete recovery without residual pain or weakness is the rule. Recovery usually occurs within weeks but in some cases may not be complete until the underlying growth plate is closed. However, if the patient reaches skeletal maturity and is still symptomatic, consideration should be given to surgical removal of the tibial tubercle or the bony ossicle overlying the tibial tubercle (or both).

Sever's Disease

Sever's disease is an apophysitis of the calcaneus due to traction by the gastrocnemius-soleus complex. It initially was described in 1912[85] and commonly is manifested as posterior heel pain in an 8- to 13-year-old athlete. It is bilateral in 60% of cases. As with other apophyseal injuries, pain is exacerbated by activity. Sever's disease can be associated with growth or tight heel cords or other biomechanical abnormalities. Impact sports, especially those that involve running, and sports in which cleats are worn frequently are implicated in the development of Sever's disease.

Patients have pain at the insertion site of the Achilles tendon and plantar fascia on the calcaneus. Tenderness is elicited when the calcaneus is squeezed bilaterally. Dorsiflexion of the ankle is restricted by tight heel cords. Radiographs may be normal in appearance or may show partial fragmentation and increased density of the calcaneal apophysis, although these findings also can be seen in normal feet.

As in Osgood-Schlatter syndrome, treatment of Sever's disease is conservative and symptomatic. Treatment consists of ice, massage, stretching of the plantar fascia and involved muscles (gastrocnemius-soleus complex and ankle invertors and evertors), nonsteroidal anti-inflammatory drugs, and addition of shock-absorbing shoe inserts. Heel cups also have been found to be helpful, but they should be accompanied by stretching to avoid exacerbation of the calf muscle contracture. Patients in whom conservative management fails have been found to have bone bruising and edema in the calcaneal metaphysis and apophysis, suggesting that calcaneal stress fractures may be the cause of persistent heel pain. Modification of activity and a trial of crutches for 3 to 4 weeks may be necessary.[86] Plantar fasciitis can cause heel pain as well, but patients will experience tenderness along the

www.ketabpezeshki.com 66485457-66963820

plantar fascia, especially at the attachment of the fascia to the calcaneus. Treatment involves the use of anti-inflammatory agents, rest, and relaxation of the plantar fascia with heel support pads.

Little League Elbow

Little League elbow is a term used to describe a group of injuries of the elbow, including apophysitis, medial epicondylitis, and osteochondritis dissecans of the radial head and capitellum. The injury involves an overuse phenomenon resulting in inflammation at the site where the forearm flexor muscles originate. As its name suggests, it commonly affects baseball pitchers in children's leagues and is associated with overhead arm motion. It also is seen in other skeletally immature overhand athletes, including tennis players. Little League elbow is caused by the excessive forces placed on the medial side of the elbow during the late cocking and acceleration phases of throwing.

Patients tend to be preadolescents in whom pain on the medial aspect of the elbow is associated with diminished throwing effectiveness and decreased throwing distance. Examination reveals localized tenderness and swelling over the medial epicondyle and pain with resisted flexion of the wrist. There may be a slight flexion contracture. Radiographs may be normal in appearance or may show fragmentation, sclerosis, and widening of the medial epicondylar apophysis. Treatment consists of a regimen of ice, nonsteroidal anti-inflammatory drugs, and modification of activity. Throwing is restricted until the symptoms have resolved. After resolution of the pain, the patient can begin a program of muscle stretching and strengthening, with a gradual return to throwing. Recovery usually takes 4 to 6 weeks. If pain returns during resumption of pitching, rest should be reinstituted. Patients with persistent pain, locking or decreased range of motion of the joint, or lateral elbow pain should be evaluated for avulsion fractures, loose bodies, and osteochondritis dissecans.

To minimize the risk of medial epicondylitis in children's league pitchers, the American Academy of Pediatrics recommends limiting the number of pitches to 200 per week or 90 pitches per outing[87]; however, the USA Baseball Medical and Safety Advisory Committee recommends lower pitch counts: 75 to 125 pitches per week or 50 to 75 pitches per outing, depending on age.[88] Preseason conditioning, use of proper pitching mechanics, and gradual increases in the amount and intensity of throwing are other preventive measures.

Apophysitis of the Hip

Apophyseal injuries of the hip involve sites around the hip where major abdominal and hip muscles either originate or insert: the anterior superior iliac spine, the anterior inferior iliac spine, the iliac crests, and the ischial tuberosities. Dancers and distance runners most commonly are affected. Patients with apophysitis of the hip experience dull pain near the hip that is related to activity. Treatment includes strengthening and stretching of the abdominal and hip muscles and restriction of activity.

Avulsion Fractures

Apophysitis tends to have an insidious onset; therefore, any patient with sudden onset of apophyseal pain after an acute traumatic event should be evaluated for an avulsion fracture of the apophysis or the adjacent bone. Such fractures occur when the muscle attachments to the apophyses are pulled off during strong active contractions against resistance, such as with a single powerful throw. Examination will reveal localized tenderness and swelling. The diagnosis usually is readily apparent on plain films (Fig. 176-27); however, bone scan and ultrasonography may play a role when the diagnosis is in question. Ultrasonography is advantageous because it involves no radiation exposure, it can detect a fracture before the development of an ossification center, and it provides a dynamic examination. Findings consistent with an avulsion fracture include a hypoechogenic zone, increased distance to the apophysis, dislocation of the apophysis, and mobility of the apophysis on dynamic examination.[89] Treatment of an avulsion fracture is based on the degree of separation. If the displacement is minimal (less than 2 cm with a hip avulsion and less than 5 mm with avulsion of the medial epicondyle[90]), immobilization for 4 to 6 weeks with subsequent slow resumption of activities usually is sufficient. With widely separated avulsion fractures, some experts recommend open reduction and fixation.[90]

KEY CONCEPTS

- Knowledge of the pediatric musculoskeletal system is imperative for appropriate evaluation and treatment of the skeletally immature patient.
- Child abuse should be suspected in children younger than 3 years with nonsupracondylar humerus fractures, femur fractures, rib fractures, and complex skull fractures.
- Children with displaced supracondylar fractures are at significant risk for neurovascular injury and should have frequent evaluations to assess for compartment syndrome.
- All children who are not yet walking should have a thorough hip evaluation on any visit to the ED.
- All patients with a gait disturbance need a thorough physical examination and directed laboratory and radiographic evaluation.
- Septic arthritis constitutes a medical and surgical emergency that mandates immediate orthopedic consultation.
- Examination of the hip is warranted in all patients with knee pain.

Section Two
THE PREGNANT PATIENT

Chapter 177
General Approach to the Pregnant Patient

Laurie J. Morrison, Alina Toma, and Sara H. Gray

PERSPECTIVE

Remarkable trends in the epidemiology of fertility have emerged that may have an impact on the demographic and diagnostic profile of patients encountered in today's emergency department (ED). The birth rates and fertility rates for all races and the mean age at menarche in both the United States and Canada have fallen during the past decade. The age-specific fertility rate has declined in women younger than 30 years, and the rate of multiple births is rising.

The 2008 report from the U.S. National Center for Health Statistics noted that the birth rate for women younger than 25 years, the principal childbearing age, had fallen from 43% in 1990 to 34.4% in 2009.[1] The overall birth rate for teens aged 15 to 19 years dropped from 15% in 1990 to 10% in 2009,[1] which resulted in a historic low of 66.7 pregnancies per 1000 women.[2] Nearly half of all pregnancies in the United States occur among unmarried women, and this number is rising, increasing from 2.7 million in 1990 to 2.8 million in 2004, whereas rates among married women continue to fall, from 4.1 million in 1990 to 3.5 million in 2004 (newer data do not exist at the time of publication). Pregnancy outcomes in the United States vary across the black, Hispanic, and white populations. The rate of pregnancies resulting in live births is highest in Hispanic women (98%) compared with non-Hispanic whites (69%) and non-Hispanic blacks (50%), whereas the rate of pregnancy resulting in abortion is highest in non-Hispanic blacks (37%) compared with non-Hispanic whites (12%) and Hispanic women (19%).[1] The median age at menarche for adolescent American girls fell from 15.5 years in 1900 to 12.3 years in 2000[3] (Fig. 177-1).

From 1980 to 2008, the number of twin births in the United States rose more than 100% (from 68,339 to 138,660), and triplet and higher order births rose just less than 400% (from 1377 to 6268 births).[2] At the same time, differences in twin birth rates between non-Hispanic white and non-Hispanic black mothers disappeared. Non-Hispanic white women were more than twice as likely as non-Hispanic black or Hispanic women to have a triplet birth.[2]

Maternal mortality related to complications of pregnancy and childbirth in the United States has slowly been declining during the past several years from 2960 maternal deaths in 1950 to 548 deaths in 2007.[4] The highest number of deaths is attributed to women older than 35 years, with 32 deaths per 100,000 live births, which is four times the rate for women 29 years of age and younger.[2] The most common causes of death are pulmonary embolism, diseases of the circulatory system, and postpartum hemorrhage.[5]

Rates of elective cesarean deliveries in industrialized countries are continuing to rise secondary to a common perception of safety and potential benefits of elective low-risk cesarean delivery compared with vaginal delivery. In Canada, the rate of planned cesarean deliveries has increased to 26% in 2003 compared with 5% in 1969.[4] A retrospective cohort study, which evaluated more than 2.3 million healthy pregnant patients, demonstrated a composite severe morbidity of 27 per 1000 deliveries for planned cesarean delivery for breech presentation versus 9 per 1000 deliveries for planned vaginal delivery for any reason, respectively.[4] Furthermore, although the study showed an increased risk of maternal cardiac arrest of 2% in the planned cesarean delivery group and 0.4% in the vaginal delivery group, the difference in the rate of in-hospital maternal death was nonsignificant ($P = .87$). Decisions about planned cesarean sections for other than conventional indications require a discussion of the risks and benefits of this intervention.

Statistical data concerning pregnant patient demographics and frequency of use of the ED and the diagnostic profile are incomplete because most observational data sets group perinatal and pregnancy as "other medical diagnosis," which accounts for less than 2% of visits to the ED in the United States and Canada[5]; however, persons between the ages of 18 and 44 years account for approximately 22% of all ED visits, so the risk of an unknown pregnancy complicating the diagnosis may be higher than anticipated.[6] A study of random pregnancy tests performed on female trauma patients revealed that 2% were pregnant.[7,8] Even when the chance of pregnancy was remote, female patients seeking treatment in the ED had a pregnancy rate of at least 10%.[7]

Maternal cardiac arrest is rare, although recent data from the Confidential Enquiries into Maternal and Child Health data set show a maternal cardiac arrest frequency that is on the rise with a current rate of 1:20,000 pregnancies, up from the previous rate of 1:30,000.[9]

Pregnant patients may present with symptoms and signs related to an undiagnosed, normal pregnancy (abdominal discomfort, nausea, urinary frequency, breast swelling and tenderness, fatigue, or near-syncope), symptoms and signs related to complications of pregnancy (see Chapter 178), or clinical manifestations of chronic medical illnesses that may be exacerbated by pregnancy (see Chapter 179). This chapter covers the following aspects of a normal pregnancy: common initial signs and symptoms, diagnostic tests, and considerations for treatment and referral.

Definitions

Gravidity refers to the number of pregnancies that the patient has had. This number includes all normal and abnormal pregnancies, including the current one.

Parity is the total number of times that the patient has given birth, regardless of outcome. Multiple births are counted

www.ketabpezeshki.com 66485457-66963820

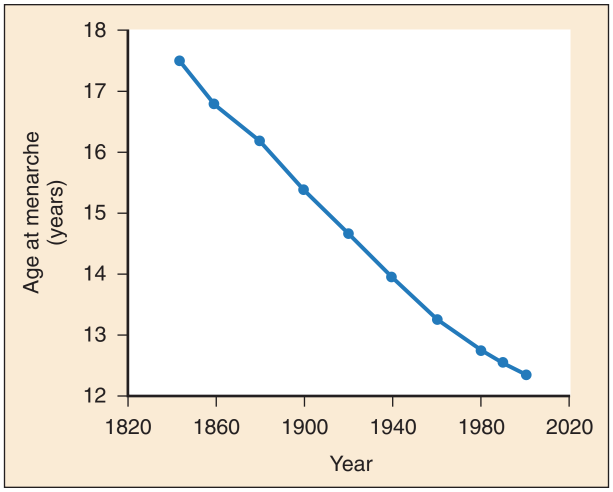

Figure 177-1. Age at menarche among European girls during the past 150 years. (Modified from Tanner JM: Growth at Adolescence. Oxford, Blackwell, 1962; Cunningham FG, et al: Williams Obstetrics, 19th ed. Norwalk, Conn, Appleton & Lange, 1993; and MacDonald PC, et al: Recurrent secretion of progesterone in large amounts: An endocrine/metabolic disorder unique to young women? Endocr Rev 12:372, 1991.)

individually for the purpose of calculating parity. *Grand multiparity* refers to a woman who has had five or more births. Parity can be divided into four distinct categories; they usually are written on the chart parenthetically, adjacent to the parity level, and separated by hyphens. The four categories are identified by the letters T-P-A-L and refer to numbers of term infants, preterm infants, abortions, and children currently living (e.g., G10 P9 [6-1-2-7]).

Gestational age refers to the number of completed weeks of pregnancy from the last menstrual period. A *term infant* is a child born between 38 and 42 completed weeks of gestation, a *preterm infant* is born before 38 completed weeks of gestation, and a *postterm infant* is born any time after 42 weeks of gestation. The conceptus is considered an *embryo* from conception until after the eighth week, when it is termed a *fetus*. An *abortus* is a fetus or embryo removed or expelled from the uterus during the first half of gestation (20 weeks or earlier) and that weighs less than 500 g or measures less than 25 cm. *Premature* labor occurs before 37 weeks of gestation, and *postmature* labor occurs beyond 42 or 43 weeks of gestation.

CLINICAL FEATURES

History

It is prudent practice to suspect pregnancy in all female patients of childbearing age presenting to the ED. Cyclic ovulation occurs on average for 38 years. Of a possible 10,000 ovarian follicles, 500 achieve ovulation. Thus there are 500 opportunities for pregnancy which likely can be achieved by sexual intercourse on any one of 1500 days. Physicians of all specialties must be constantly vigilant and sensitive to the possibility that women of reproductive age may be pregnant irrespective of their presenting complaint.

The reliability of the sexual and menstrual history has been notably poor. Ramoska and colleagues reported that 11.5% of women with abdominal pain or vaginal bleeding had positive pregnancy test results, in contrast to their perception that there was "no chance" they were pregnant.[7] Missed diagnosis of pregnancy in adolescents was associated with failure to document a sexual or menstrual history. Adolescents rarely mentioned the possibility of pregnancy at triage (10% of those found to be pregnant), and 10% of those with a positive pregnancy test result denied being sexually active.[10] Interestingly, pregnancy rates in adolescents continue to rise in the United States, with estimates of 42.5 per 1000 women of this age group, and have increased 5% from 2005-2007 data.[1] Thus one should have a high index of suspicion of pregnancy in adolescents who present with symptoms of pregnancy, which include cessation of menses, anorexia, nausea, easy fatigability, urinary frequency, breast swelling and tenderness, and perception of fetal movement or "quickening" (beginning at 16 to 20 weeks).

Cessation of menses becomes suggestive of pregnancy at 10 days or longer after the time that menstruation is expected. Intermittent, spontaneous vaginal bleeding or vaginal discharge is common during the first half of pregnancy, particularly in multiparous women. Most women without cervical lesions experience bleeding on or before the 40th day of pregnancy. This bleeding has been interpreted by some investigators to be physiologic in origin and a result of implantation.[11] Nevertheless, any patient presenting with vaginal bleeding during pregnancy should be considered to be at risk for a pathologic cause of the bleeding.

It is possible to calculate the estimated date of delivery in a regularly menstruating woman who has 28-day cycles and can give a reliable history. Franz K. Nägele, a German obstetrician in the 18th century, developed Nägele's rule, which is still the current standard: add 7 days to the date of the first day of the last menstrual period and subtract 3 months. Currently, with the increasing use of smart phones, hand-held devices, and the Internet, literally hundreds of calculators are available to clinicians to aid in the estimation of delivery date. In the absence of reliable recall of the first day of the last menstrual period, first-trimester ultrasonography may estimate the date of delivery. Ultrasonography dating is most accurate if it is done between 10 and 12 weeks.[12]

Physical Examination

During the last half of pregnancy, the physical examination should be done with the patient in the left lateral recumbent position to avoid precipitation of the supine hypotension syndrome.

Vital signs in a pregnant patient are essentially the same as those in a nonpregnant patient. The only changes are seen in the heart rate and blood pressure. The resting heart rate increases approximately 10 to 15 beats/minute, and blood pressure demonstrates a mean arterial decrease of 6 to 10 mm Hg, which reaches a nadir in mid–second trimester and slowly increases to the patient's nonpregnant value by term. Blood pressure in the brachial artery is highest in the sitting position, lowest when lying in the left lateral position, and intermediate in the supine position, except in pregnant women who have supine hypotension syndrome. Pathologic hypertension of pregnancy is defined as a sustained rise of 30 mm Hg systolic or 15 mm Hg diastolic above baseline values on at least two occasions, 6 hours or more apart. A study demonstrated a steady increase in prevalence of hypertension in pregnant women from 67 per 1000 pregnant patients in 1998 to 83 per 1000 patients in 2006. The highest risk cohort is women older than 35 years, with a reported rate of 89 per 1000 patients.[13] The authors concluded that hypertension and related illnesses are major risk factors for severe obstetric morbidity. Furthermore, as more women have children later in life, in addition to the increasing prevalence of obesity, the number of patients with hypertension-related illness due to pregnancy will most likely continue to rise.[13]

Fetal heart activity should be included as the fifth vital sign in the evaluation of a pregnant patient. It can be auscultated with a stethoscope at 17 weeks of gestation on average and by 19 weeks in nearly all pregnancies in nonobese women. With the use of Doppler ultrasonography, fetal cardiac activity can be detected as early as 8 weeks; however, it is more commonly heard by 10 weeks.

www.ketabpezeshki.com 66485457-66963820

With improved transvaginal ultrasonography technology, it has been possible to detect fetal cardiac activity in embryos as small as 6 mm.[14]

Auscultation of the pregnant abdomen reveals numerous findings that may be confusing. In addition to fetal heart sounds, it may be possible to identify sounds of fetal movement, the maternal pulse, maternal bowel sounds, and the fundic and uterine souffle. The fundic or umbilical cord souffle is created by blood rushing through the umbilical arteries. The resultant whistling sound is timed with the fetal pulse and is present in 15% of pregnancies. The uterine souffle is a soft blowing sound timed with the maternal pulse, usually heard in the lower portion of the uterus. It is a function of blood flow through the dilated uterine vessels and can be heard in pregnancy and in women with uterine myomas or large tumors of the ovaries.

Breast tenderness and fullness are common manifestations of pregnancy that can be appreciated on gentle physical examination. Objective breast changes include darkening of the areolae, greater prominence of the glands of Montgomery around the nipple, engorgement of the breasts with tiny bluish venules, and presence of colostrum at the nipple with gentle massage of the breasts. This milky material may persist for months or even years, especially if the patient continues to breast-feed.

Increased skin pigmentation (melasma gravidarum) and abdominal striae occur not only in pregnancy but also in women who ingest estrogen-progestin contraceptives.

Braxton-Hicks contractions are painless contractions that begin in early pregnancy and occur spontaneously and irregularly throughout the pregnancy. They also occur in patients with hematometra and those with uterine myomas. These contractions are not reliable for the diagnosis of pregnancy; however, they do not occur in ectopic pregnancy.

Uterine enlargement can be felt in nonobese women. At 6 to 8 weeks, the uterus is approximately the size of an orange. At 12 weeks, the top of the fundus should be at the level of the symphysis pubis; at 16 to 20 weeks, at the level of the umbilicus; and at 36 to 38 weeks, at the level of the xiphoid process of the sternum. Thereafter, the fetus descends into the pelvis, and fundal height may decrease accordingly.

Hegar's sign, which is softening of the lower uterine segment caused by hyperemia, can be appreciated during an internal pelvic examination at approximately 6 to 8 weeks of pregnancy. In some cases the softening is sufficient to allow the examiner to easily distinguish the cervix from the fundus on palpation. It can be found in other conditions, but it is not as easily detected as it is in pregnancy (Fig. 177-2).

The vaginal mucosa becomes hyperemic during pregnancy and with any other condition that causes congestion of the pelvic organs. In response, the color of the mucosa of the vaginal walls changes from pink to blue to violet and can be visualized at the vaginal introitus (Chadwick's sign).[15]

At midpregnancy the fetus can be detected by ballottement or palpated through the maternal abdominal wall in a nonobese patient. The fetus floats in a large volume of amniotic fluid. Thus, with ballottement, pressure exerted on the uterus causes the fetus to sink and then to rebound to its original position. Palpation of the outline of the fetal body becomes easier near the end of pregnancy; however, subserosal myomas can simulate the fetal head and small parts, or both.[10]

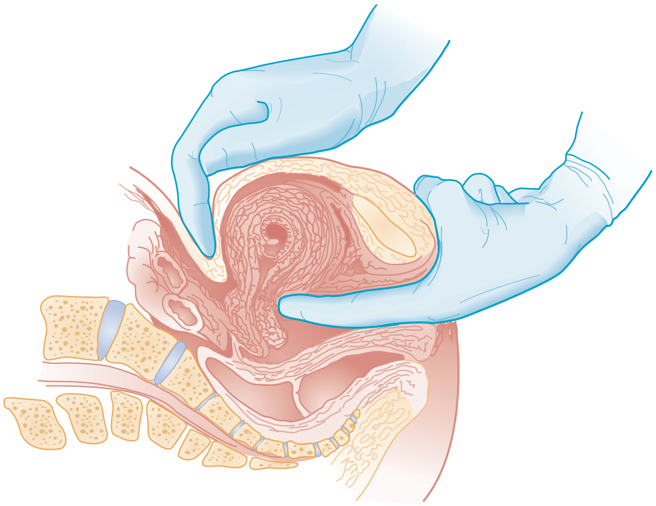

Figure 177-2. Hegar's sign. The softness and compressibility of the lower uterine segment can be so extreme that the fundus and cervix may even feel like separate organs. (Modified from Willson JR, et al: Obstetrics and Gynecology, 5th ed. St Louis, CV Mosby, 1975.)

DIAGNOSTIC STRATEGIES

Laboratory Tests

Determination of the urine or serum level of human chorionic gonadotropin (hCG) is important in clinical management. Applications include diagnosis and monitoring of pregnancy and diagnosis and evaluation of the course of neoplastic trophoblastic disease or response to treatment (i.e., hydatidiform choriocarcinoma, gonadal teratoma, a carcinoma with ectopic secretion of hCG).

The hCG assays are referenced to standard hCG preparations. Thus the reference standard should always be noted in comparison of results. One nanogram of hCG equals 9.3 mIU of the international reference standard provided by the World Health Organization (used in this chapter) and equals 5.0 mIU of the second international standard.

Biologic assays for hCG are now only of historical interest. Since the 1960s, all hCG assays have been immunoassays. Enzyme-linked immunosorbent assay (ELISA) for hCG is the state-of-the-art pregnancy test. It offers greater user convenience and has a sensitivity for levels of hCG between 25 and 50 mIU/mL.

The pregnancy test has undergone a number of refinements over the years. Antibodies are selected that act against the purified beta subunit of hCG, and this modification has resulted in improved sensitivity for low levels of hCG in the presence of luteinizing hormone. The development of monoclonal antibodies has improved specificity for the purified beta subunit of hCG.

The fundamental process of ELISA involves an antibody adherent to a solid-faced support (usually plastic) that binds to a region of the hCG molecule. A second antibody chemically linked to an enzyme (e.g., alkaline phosphatase) binds to another side of the trapped hCG molecule. The hCG molecule is sandwiched between the two antibodies. Excess enzyme-linked antibody is washed away, and a color developer is added and becomes blue when it comes in contact with the enzyme (Fig. 177-3). The antibodies can be polyclonal or monoclonal. Many variations exist with respect to the solid-faced support and the method of developing the color reaction.

In 1988 the first one-step pregnancy test became available. It was developed and patented by Unipath and sold as Clearblue One Step. This test uses monoclonal antibodies specific for the beta subunit of hCG. It includes a unique built-in control that shows a blue line when the test is complete and performed correctly.[16] This test appeals to consumers because it is rapid (requiring less than 5 minutes), requires no manipulation by the user, offers hygienic sample handling, provides clear and easy-to-read results, and has a sensitivity level of hCG between 25 and 50 mIU/mL. This level of sensitivity means that more than 95% of pregnancies

www.ketabpezeshki.com 66485457-66963820

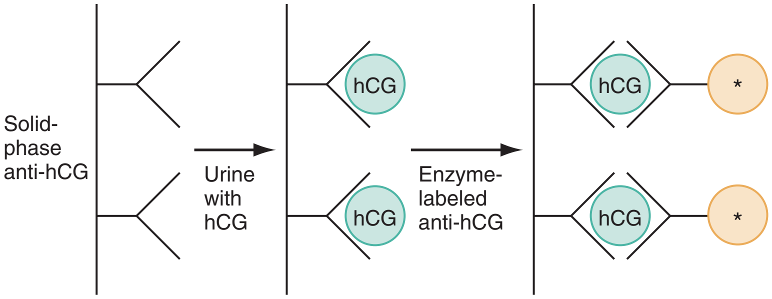

Figure 177-3. The principle of enzyme immunoassay (also sometimes known as sandwich or immunometric assay). *hCG,* human chorionic gonadotropin. (Modified from Chard T: Pregnancy tests: A review. Hum Reprod 7:701, 1992.)

within 3 days after missed menses will be detected by a home pregnancy device.[17] For detection to occur on the day of missed menses, a lower sensitivity level of 12.5 mIU/mL is required. A study in 2001 compared routine urinary hCG point-of-care qualitative tests performed by nurses in the ED with laboratory tests and found the former to be equally accurate and much faster, shaving 35 minutes off wait times for results.[18]

A well-designed ELISA applied to urine is not affected by drugs or a concurrent physiologic state. The only exception is patients taking exogenous hCG for induction of ovulation.[19]

Normal hCG levels in men and premenopausal women range from 0.02 to 0.8 mIU/mL. Postmenopausal women may have higher levels.[20] The blastocyst begins to secrete hCG 7 days after fertilization.[21] Thus the hCG released can be detected as early as 6 to 8 days after conception.[22]

The initial doubling time is fast and has been attributed to the actual process of implantation. This is followed by a slower rate of doubling as trophoblast hCG and maternal circulatory hCG levels equilibrate[22] (Fig. 177-4). Levels of hCG peak at 7 to 10 weeks of pregnancy, with a mean value of 50,000 mIU/mL and a range of 20,000 to 200,000 mIU/mL.[21]

The test results for hCG become positive in 98% of patients 7 days after implantation, which coincides with the time of the expected period. When a test with a sensitivity of 25 to 50 mIU/mL is used, a negative result 1 week from the expected time of the missed period essentially guarantees that a woman is not pregnant.[19]

False-positive results can be attributed to postmenopausal status, abortion in the first trimester, exogenous hCG for induction of ovulation, or hCG-secreting tumor. Levels of hCG may take as long as 60 days to return to zero after an abortion.[23] Failure to decline during 60 days and persistent elevation of hCG beyond 60 days after abortion may indicate an incomplete abortion, a twin pregnancy with only one fetus removed, or an ectopic pregnancy.[1]

The hCG assay continues to be the standard for the diagnosis of pregnancy. Routine clinical detection of pregnancy by ultrasonography is not possible until at least 5 weeks' gestation, when the hCG level is 1000 mIU/mL or more.[24-26]

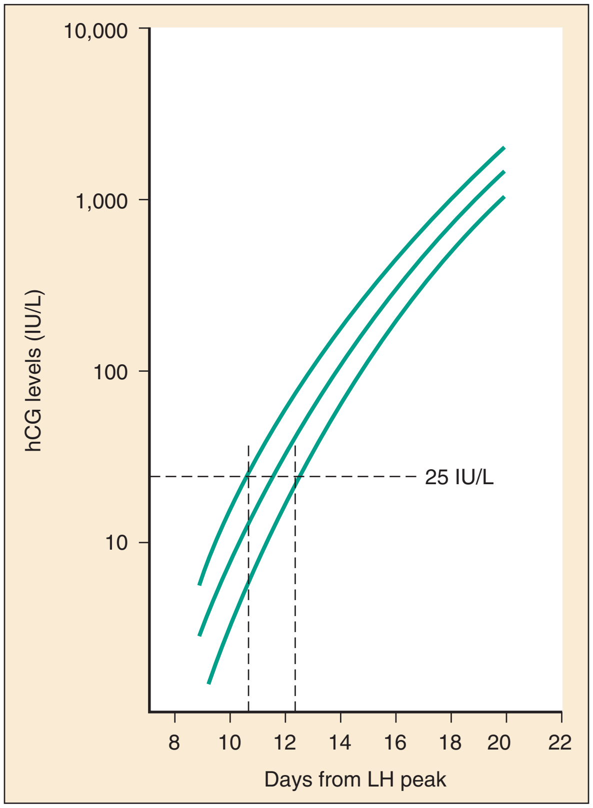

Figure 177-4. Levels of circulating human chorionic gonadotropin (*hCG*) in early pregnancy, showing that an assay with a sensitivity level of 25 mIU/mL would yield a positive result in some subjects between 10 and 11 days after the peak in luteinizing hormone (*LH*) and in most subjects at 12 to 13 days after the peak. (Modified from Chard T: Pregnancy tests: A review. Hum Reprod 7:701, 1992.)

Radiology

Ultrasonography

Ultrasonography is reliable for the diagnosis of intrauterine pregnancy during the first trimester. Systematic reviews demonstrate that ultrasonography scans performed in the ED have a sensitivity of 90% and specificity of 98% in the detection of an intrauterine pregnancy.[27] In addition to diagnosis, it also locates the embryo and assesses gestational age and viability. Transabdominal sonography is more commonly used; however, transvaginal sonography may be necessary during the first trimester if transabdominal sonography is not diagnostic.

Sonography during the second trimester is used to survey fetal anatomy. The anatomic survey includes the cerebral ventricles, four-chamber view of the heart, spine, stomach, urinary bladder, umbilical cord insertion on the abdominal wall, and kidneys.[28]

Much debate exists about whether ultrasonography should be performed as part of routine prenatal screening in all pregnancies. The American College of Obstetricians and Gynecologists (ACOG) recommends that all physicians discuss the benefits and limitations of ultrasonography with patients and come to a decision together about the screening examination.[28] Although prenatal screening is still an object of contention, the ACOG states that there is good evidence for the safety and accuracy of

www.ketabpezeshki.com 66485457-66963820

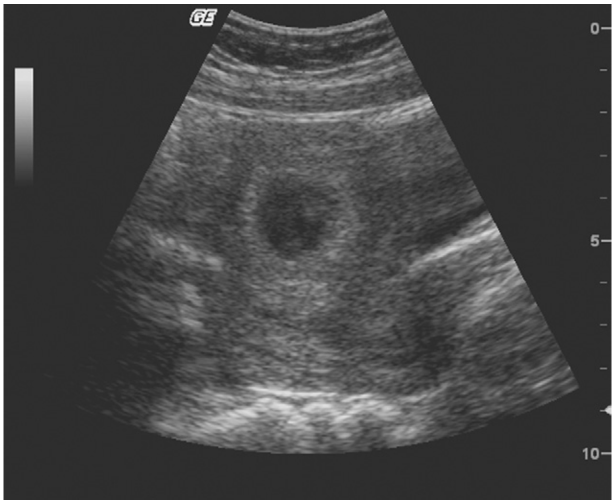

Figure 177-5. Transabdominal ultrasonography image showing a gestational sac with no fetal pole or yolk sac. (Courtesy Andrew A. Common, MD.)

ultrasonography examination to determine gestational age, major fetal anomalies, fetal number, viability, and placental location and recommends the test if these areas are in question.[28] First-trimester ultrasonography, in conjunction with biochemical parameters, is an integral part of first-trimester genetic screening for aneuploidy and is usually performed at 11 to 13 weeks of age.

Transabdominal Sonography. At 6 weeks the gestational sac can be visualized by transabdominal sonography (Fig. 177-5). This sonographic finding disappears after the 11th week of gestation. Presence of the gestational sac is confirmed when two central uterine echoes are visualized within the hypertrophied endometrium. This diagnostic echo is called the double ring sign. The gestational sac is eccentrically positioned within an asymmetrically thickened decidua. A healthy pregnancy can be determined by correlating the size of the sac with gestational age and quantitative hCG values. At 8 weeks the fetal pole and fetal heart activity can be visualized reliably with transabdominal ultrasonography in a normal pregnancy. Diagnosis of an intrauterine pregnancy with ultrasonography can be made with the following findings: yolk sac or fetal pole visualized inside myometrium, bladder-uterine juxtaposition confirmed, and myometrial mantle of 5 mm[29] (Fig. 177-6). Diagnosis of a live intrauterine pregnancy also requires visualization of intrauterine fetal heart activity.

Transvaginal Sonography. Transvaginal sonography affords greater resolution than transabdominal sonography and does not require a full bladder. Transvaginal ultrasonography examination can identify an intrauterine gestational yolk sac at 4 to 5 weeks' gestation. Fetal heart motion can be detected with transvaginal ultrasonography evaluation at 6 weeks' gestation.

An intrauterine pregnancy can be diagnosed by sonographic findings in the following order of appearance: the double ring sign, the double gestational sac, the intrauterine fetal pole, and intrauterine fetal heart activity (see Fig. 177-6).

Magnetic Resonance Imaging

No significant side effects have been documented to date with the magnetic field and radio waves used in magnetic resonance imaging (MRI). Gadolinium is the most common intravenous contrast agent, and allergic reactions with this agent are rare. Currently, the ACOG recommends that nonionizing imaging procedures like MRI and ultrasonography be used preferentially, when appropriate, and they are not known to be associated with adverse fetal effects.[30]

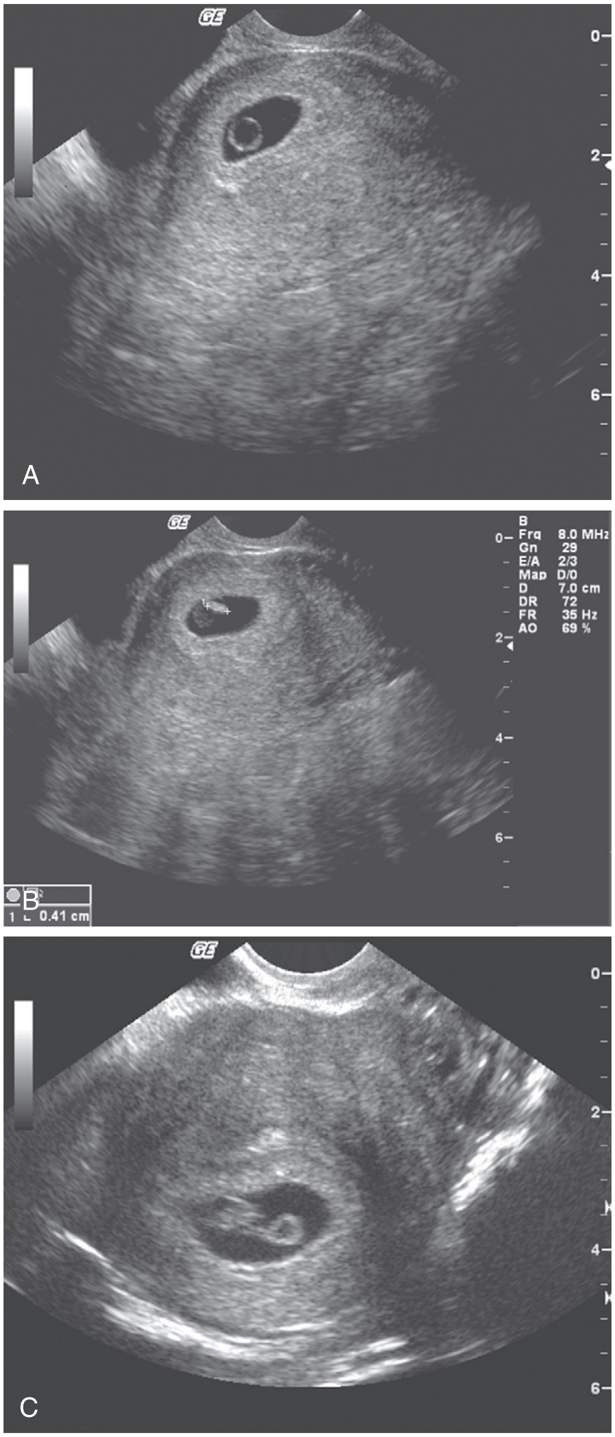

Figure 177-6. Transvaginal ultrasonography images. **A,** Yolk sac. **B,** Fetal pole. **C,** Fetal pole, vitelline duct, and yolk sac. (Courtesy Andrew A. Common, MD, and Derek Muradali, MD.)

Plain Radiographic Fetal Identification

The fetus can be reliably recognized by plain radiography after 16 weeks' gestation. Fetal foci of ossification can be identified as early as 14 weeks.

Diagnostic Imaging Considerations in Pregnant Patients

The decision to perform imaging investigations in a pregnant patient must take into consideration the risk to the developing

www.ketabpezeshki.com 66485457-66963820

fetus from radiation exposure and the inherent risks with such investigations for the mother, balanced with the risk to the mother and fetus associated with missing the diagnosis because of reluctance to use available diagnostic imaging techniques. The potential for adverse outcomes with intrauterine fetal exposure to the radiation used in radiography is minimal.[31] Case-control studies report a slight but statistically significant increase in the relative risk for childhood cancer.[32] Radiation is a dose-dependent teratogen.[33] The fetal central nervous system is most vulnerable to the teratogenic effects of radiation at 8 to 15 weeks after conception. The fetal dose of radiation is estimated from the ovarian or uterine dose. Pregnant women exposed to less than 50 mGy have pregnancy outcomes similar to those of control subjects.[34] A study of childhood cancers in the offspring of female radiologists revealed a cancer frequency of 0.16% in children exposed to 10 mGy of radiation in utero. In comparison, the frequency of cancer is 0.07% among children who were not exposed to radiation in utero.

Table 177-1 summarizes the estimated fetal radiation exposure associated with the more common diagnostic imaging modalities. Radiation exposure depends on the equipment and technique, and estimates listed may not be generalizable to every radiology department.

A thoughtful, common-sense approach to the differential diagnosis will provide a sound basis for imaging investigations that will undoubtedly be in the best interests of the mother and the fetus. It is important not to defer investigations that are medically necessary, so long as the anticipated fetal doses are less than 50 mGy.[35]

Table 177-1 Fetal Radiation Exposure with Various Imaging Modalities

PROCEDURE	ESTIMATED FETAL RADIATION EXPOSURE (μGy)
Chest plain film with an abdominal shield	10*
Chest CT with an abdominal shield	100*
Abdomen plain film	2400*
Abdomen CT: with and without contrast agent	20,000 and 10,000*
Cardiac catheterization: with and without pelvic fluoroscopy	13,000 and 1000*
Head CT	100*
Unilateral venography without an abdominal shield	3050
Limited venography with an abdominal shield	500
Pulmonary angiography via femoral access	4050
Pulmonary angiography via brachial access with an abdominal shield	500
Perfusion lung scan using ^{99m}Tc-MAA	
3 mCi	180
1-2 mCi	60-120
Ventilation lung scan using	
^{133}Xe	30-200
^{99m}Tc-DTPA	70-350
^{99m}Tc-SC	10-50
Ventilation-perfusion scan	500

DIFFERENTIAL CONSIDERATIONS

Considerations in the differential diagnosis with early pregnancy include myomas, hematometra, adenomyosis, and extrauterine mass or masses. Patients with these diagnoses, excluding hematometra (a blood collection or retention in the uterus), typically have persistent regular menses. The enlarged uterus in these nonpregnant conditions generally is firmer and less elastic and boggy than it is in pregnancy.

Spurious pregnancy is imaginary pregnancy or pseudocyesis (false phantom). It usually occurs in women nearing menopause or in women who have an overwhelming desire for pregnancy. The associated increase in abdominal girth generally is attributable to fat deposition, fluid accumulation, or intestinal gas. The menses may become unpredictable with respect to timing, duration, and amount of flow. This condition can be associated with changes in the breasts, including enlargement, galactorrhea, and increased areolar pigmentation. Patients may have morning sickness of psychogenic origin. The associated use of phenothiazines may cause amenorrhea, hyperprolactinemia, breast enlargement, and galactorrhea. Women with this condition may perceive fetal movements. Most commonly these movements can be attributed to muscle contractions of the abdominal wall and normal gastrointestinal peristalsis.

The diagnosis is confirmed by the presence of a small uterus and a negative pregnancy test result. The challenge in this condition is to convince the affected woman of the lack of pregnancy and to address the underlying reason for the delusion.

SPECIFIC DISORDERS

Perspective

In general, a pregnant patient should be treated and assessed in the same way as all other patients are. However, the normal physiologic changes of pregnancy may mask or unmask underlying medical conditions. Thus it is important to ascertain whether the presenting complaint is due to the pregnancy, an unrelated problem that is affected by the pregnancy, or a problem that affects the pregnancy.[36] In addition, consideration should be given to the increased medical risks of pregnancy (e.g., deep venous thrombosis) and risk to the fetus associated with diagnostic imaging or surgical interventions.

Headache

The most common headache during pregnancy is a muscle contraction headache.[37] The patient usually has had a history of headaches before the pregnancy. The headaches begin on waking and increase in intensity during the day. The headache is described as a broad band, squeezing or constricting in quality, and localized to the vertex. The paracervical muscles are taut, and palpation usually reproduces or exacerbates the pain. During pregnancy these headaches are worsened by postural changes and psychosocial stress. Commonly used abortive medications for migraines in pregnancy include acetaminophen (e.g., Tylenol), aspirin, opioids, triptans, antiemetics, and caffeine.[37] From 18 to 86% of classic migraine sufferers experience remission from attacks during pregnancy, particularly women with menstrual migraines.[37,38] Therefore, any headache in a pregnant patient requires investigation, except a typical headache in a patient with a known primary headache disorder.[37,39]

www.ketabpezeshki.com 66485457-66963820

Brain tumors enlarge during pregnancy and shrink temporarily postpartum.[40] Most brain tumors become symptomatic during the second half of pregnancy, and they account for 10% of maternal deaths during pregnancy. Both pituitary gland and prolactin-secreting adenomas swell during pregnancy. Headache usually develops during the first trimester and precedes visual changes by approximately 1 month.[40] On occasion, central venous thrombosis may occur during pregnancy and mimic eclampsia. The lack of proteinuria and hypertension points to central venous thrombosis.[37] Central venous thrombosis is an unusual cause of postpartum headache that is associated with a mortality rate of 40%.[37]

Pseudotumor cerebri is benign intracranial hypertension in the absence of a mass lesion and hydrocephalus. Symptoms and signs often include headache and papilledema. Other associated findings include decreased visual acuity, loss of color vision, defects in visual fields, and horizontal diplopia caused by abducens nerve palsy. Pseudotumor cerebri associated with pregnancy usually occurs in obese women and begins during the third to fifth months of pregnancy. Symptoms resolve spontaneously after 1 to 3 months.[41]

Spontaneous subarachnoid hemorrhage accounts for 10% of maternal deaths. Reviews of the risk for subarachnoid hemorrhage in pregnant versus nonpregnant patients have been conflicting. The absolute risk has been estimated to be 1 in 2000 to 10,000. In a majority of cases, the intracranial bleeding is attributable to rupture of an arteriovenous malformation or a ruptured intracranial aneurysm. The overall risk for rupture of an arteriovenous malformation is identical in pregnant and nonpregnant patients without previous bleeding.[42] Arteriovenous malformations usually bleed during the second trimester and during labor. Berry aneurysms typically bleed during the third trimester, and the incidence of bleeding increases as the pregnancy advances.

Nearly one third of cases of subarachnoid hemorrhage are a result of bleeding disorders, bacterial endocarditis, metastatic tumor, and sickle cell disease. Cerebral hemorrhage is the most common cause of death in toxemia. It occurs in 60% of patients who die after becoming eclamptic.

New-onset headache or a change in the usual pattern of headache pain during pregnancy or the postpartum period warrants a closer look. A thorough history and a detailed physical examination with emphasis on visual field and funduscopic examination can, in most cases, exclude the aforementioned serious disorders.

Chest Pain

The diagnosis of cardiac disease is complicated by the fact that the signs and symptoms of a normal pregnancy are suggestive of heart disease. Pregnancy is associated with easy fatigability, dyspnea, orthopnea, palpitations, syncope, peripheral edema, chest discomfort, and reflux. Triggers for further cardiac evaluation include progressive orthopnea, dyspnea severe enough to limit activity, paroxysmal nocturnal dyspnea, syncope during or immediately after exertion, hemoptysis, and chest pain in an ischemic distribution at rest or associated with exertion, anxiety, or anger.

Cardiovascular findings are altered in normal pregnancy. Peripheral edema is present in 80% of pregnant women. A third heart sound and systolic murmurs are common. Diastolic murmurs and systolic murmurs of grade higher than 2/6 warrant investigation. Other worrisome signs include cyanosis, clubbing, pulmonary rales, distended neck veins throughout the cardiac cycle associated with hepatomegaly and peripheral edema, persistent split S_2, and criteria of pulmonary hypertension (left parasternal lift and a loud P_2).

The pregnant patient is predisposed to thromboembolic disease as a result of increased venous pressure, decreased distal venous flow, and significant venous stasis from compression of the pelvic veins and inferior vena cava by the enlarging uterus. Other predisposing factors may include the use of oral contraceptives before conception and the propensity for stasis secondary to lack of activity in the workplace and at home as the pregnancy progresses. The annual incidence of thromboembolism is five times higher in postpartum women than in pregnant women.[43] The incidence of deep venous thrombosis is three times higher than that of pulmonary embolism; however, the incidence of deep venous thrombosis during pregnancy has remained constant during the last 30 years, whereas that of pulmonary embolism during pregnancy doubled.[43] This increased risk for pulmonary embolism in pregnancy should prompt thorough evaluation of pregnant patients who present with pleuritic chest pain, syncope, acute right-sided heart failure, or more subtle signs, such as unexplained fever, dyspnea, or tachycardia.

Abdominal Pain

Displacement of the abdominal contents by the expanding uterus during pregnancy causes abdominal discomfort that may be associated with nausea, vomiting, gastroesophageal reflux, delayed gastric emptying, bowel irregularity, urinary frequency, and back and buttock pain. These findings may complicate the clinical assessment of a pregnant woman with abdominal pain. Delay in diagnosis or failure to diagnose and to treat underlying pathologic conditions may result in maternal and fetal morbidity and death.

Obstetric causes of abdominal pain early in pregnancy include vascular congestion of the pelvic tissues, round ligament tension, ectopic pregnancy, and threatened abortion. With increasing rates of infertility and use of fertility-enhancing drugs, there has been a corresponding increased incidence of women with ovarian hyperstimulation syndrome (OHSS). OHSS is an iatrogenic syndrome characterized by ovarian enlargement (from multiple ovarian cysts) and fluid shifts to the extravascular space, causing ascites, hypovolemia, and electrolyte abnormalities. Studies have suggested that in vitro fertilization treatments have been associated with up to 33% of mild forms of OHSS and 3 to 8% of severe cases.[44] Severe forms of OHSS require urgent diagnosis and treatment to mitigate the high risk of associated thromboembolic events, respiratory failure, and renal failure.

Later in pregnancy, considerations in the obstetric differential diagnosis should include Braxton-Hicks contractions, toxemia, premature labor, abruptio placentae, and rupture of the uterus. Nonobstetric causes include all diagnoses seen in a nonpregnant patient (e.g., cholecystitis, pyelonephritis, renal colic, ovarian torsion, salpingitis, corpus luteum cyst rupture or torsion, degeneration of a uterine myoma). Common surgical diseases that may complicate pregnancy include appendicitis, gallbladder disease, and intestinal obstruction.

Appendicitis is the most common surgical emergency in pregnancy.[45,46] The incidence ranges from 0.06 to 0.1%, or 1 in 1500 deliveries. Although the incidence is relatively close to that of nonpregnant patients, the perforation rate is higher during pregnancy.[46-48] The state of pregnancy results in delays in diagnosis of appendicitis that contribute significantly to maternal and fetal morbidity and mortality.[48] The perinatal mortality rate for women with nonperforated appendicitis is 4.8%. It rises, however, to 27.8% in those experiencing perforation at the time of surgery. The perforation rate is as high as 30% during the third trimester.[48]

The diagnosis of appendicitis is more difficult during the latter half of pregnancy, but it is challenging even in early pregnancy. Anorexia, nausea, and vomiting are symptomatic of appendicitis and may be misinterpreted as hyperemesis of pregnancy. As the uterus enlarges, the appendix moves upward and outward toward

www.ketabpezeshki.com 66485457-66963820

the right. As the appendix moves higher, the omentum is unable to surround the appendix and to contain the infection if rupture occurs. Thus appendiceal rupture in pregnant women results in generalized peritonitis. However, even though there is a change in the relative position of the appendix during pregnancy, the most common symptom of appendicitis is right lower quadrant pain that occurs close to McBurney's point in the majority of women regardless of the stage of pregnancy.[44,49,50] A retrospective review comparing MRI findings with surgical confirmation of disease suggested that MRI is useful for triage of pregnant patients with acute abdominal and pelvic pain.[50] When it is available, MRI should be considered in this setting of nonconclusive findings on ultrasonography, particularly during the first trimester of pregnancy, because of the higher levels of radiation exposure associated with computed tomography of the abdomen.

Musculoskeletal Pain

Hand symptoms are common during pregnancy. The median nerve is at risk for compression distally within the carpal tunnel. Approximately 25% of pregnant women complain of hand symptoms compatible with median nerve compression, but only 2.3% are actually found to have carpal tunnel syndrome.[51] Symptoms of carpal tunnel syndrome include the classic triad of burning pain, numbness, and tingling in the thenar area or median nerve distribution. The patient often is awakened from sleep with the onset of symptoms. In 80% of cases, the symptoms are bilateral. Tapping over the median nerve at the wrist (Tinel's sign) or hyperflexing the wrist (Phalen's test) reproduces the symptoms and is diagnostic. Because the symptoms usually resolve during the postpartum period, only supportive treatment is required. A sleep splint applied with the hand in slight flexion resolves the symptoms in 80% of patients.[51]

Postural changes in the cervical spine, the shoulder girdle, and the lumbar spine result in pregnancy-related posterior pelvic pain and low back pain. Lordosis is exaggerated and becomes progressively more symptomatic during pregnancy. Low back pain usually is localized to the lumbar region just above the sacroiliac joint, worsened by forward flexion at the waist, and results in decreased range of motion and tenderness to palpation of the erector spinae muscles. The pain may radiate to one or both of the legs. The nature of the referred pain lacks the radicular quality of diskogenic pain and does not extend beyond the knee. Patients should avoid wearing high-heeled shoes because this will increase the lumbar lordosis with exacerbation of the pain. Swimming and conditioning exercises are recommended. Pregnancy-related posterior pelvic pain is hypothesized to occur because of asymmetrical sacroiliac joint laxity. It is important to distinguish this from low back pain because the treatments are different. Pregnancy-related pelvic pain is a stabbing pain in the buttocks, distal and lateral to the L5-S1 area, which may or may not radiate to the posterior thigh or knee, with a normal range of motion at hips and spine. The *posterior pelvic pain provocation test* has a positive predictive value of 0.91 for pregnancy-related pelvic pain. The test is performed with the patient in the supine position with the hips and knees bent at 90 degrees. The examiner applies pressure with one hand at the knee along the long axis of the femur from anterior to posterior while using the other hand to stabilize the pelvis at the contralateral anterior iliac spine. A positive test result is gluteal pain on the side of femoral pressure.[52]

Meralgia paresthetica is a painful dysesthesia along the lateral aspect of the thigh caused by entrapment of the purely sensory lateral femoral cutaneous nerve as it passes beneath the inguinal ligament. This condition develops during the third trimester in obese pregnant women or in pregnant women with excessive and rapid weight gain. It resolves during the postpartum period without treatment.

Trauma

The ACOG reports that 1 in every 12 pregnancies is complicated by physical trauma.[53] Trauma is the leading cause of maternal death secondary to nonobstetric etiologic conditions or disorders.[54] One study suggested that fetal mortality after trauma is significantly associated with higher injury severity score (of 28 or higher), lower final hemoglobin level, higher number of transfusions, longer hospital stay, and higher incidence of disseminated intravascular coagulation.[55] A retrospective institutional review during 5 years demonstrated that older maternal age, first-trimester presentation, elevated serum lactate level, and high injury severity score were associated with poor fetal outcome.[56] Other studies have not demonstrated a correlation between injury severity scores and maternal and fetal morbidity, although the authors advocated enhanced clinical vigilance for the unexpected in caring for obstetric trauma victims (see Chapter 37).[57]

Maternal Cardiac Arrest

Maternal cardiac arrest affects 1 in every 20,000 pregnancies, with an estimated survival rate of 6.9%.[58] A number of anatomic and physiologic changes in pregnancy contribute to cardiac arrest; the most common causes are trauma, hemorrhage, embolism, eclampsia, cardiac disease, and acute coronary syndrome.[59] When a health care provider first approaches a maternal cardiac arrest, important initial measures include activation of the maternal cardiac arrest and neonatal resuscitation teams, placement of the patient supine, and initiation of chest compressions per normal basic life support algorithms.[9,59] When the maternal arrest team arrives, a member of the group should perform a manual displacement of the uterus to the left. Performance of this maneuver will help remove the gravid uterus from the inferior vena cava, thereby relieving some aortocaval compression.[9,59] Other modifications to the nonpregnant cardiac arrest are starting of intravenous lines above the diaphragm, early assessment of hypovolemia and appropriate fluid resuscitation, and termination of any magnesium intravenous therapy. While active resuscitative measures are in progress, the obstetric and neonatal teams should prepare for an emergent cesarean section if there is no return of spontaneous circulation within 4 minutes of the onset of the maternal cardiac arrest; the goal is to perform the delivery of the child at 5 minutes if maternal circulation is not restored.[9,59]

Domestic Violence

Up to 35% of all ED visits by women are due to injuries or illnesses related to domestic violence. Domestic violence is conservatively estimated to occur in 10 to 20% of North American spousal relationships. Estimates of abuse during pregnancy vary widely, ranging from 1% up to 37%. The wide variation in estimates is attributable to different study designs, definitions of abuse, and sample population demographics.[60-66] Moreover, it generally is accepted that violence in the home is under-reported and the prevalence is higher than studies estimate.

A survey taken between 2004 and 2007 of 134,955 pregnant women in the United States showed that the prevalence of violence during pregnancy is approximately 3.6%.[66] Risk factors for violence during pregnancy include a recent divorce or separation (15.6%), a partner who expresses that he did not want the pregnancy (14.6%), and being close with someone who has a substance abuse or drinking problem (12.7%).[66] Other significant demographic variables associated with abuse and pregnancy can be classified under the major headings of social instability, unhealthy lifestyle, and physical health problems.[67] Abused pregnant women are more commonly of lower educational levels, unmarried, unemployed, eating an unhealthy diet, abusing drugs

www.ketabpezeshki.com 66485457-66963820

and alcohol, and experiencing an unplanned pregnancy; they may also delay seeking of prenatal care.[67-69] Evidence of physical abuse is more common in the facial area in a nonpregnant patient, whereas blunt abdominal trauma is the most common injury type in a pregnant patient.[67,70] Blunt abdominal trauma can result in miscarriage, abruptio placentae, fetal loss, premature labor, fetal fractures, low birth weight, and premature delivery. Other common injury sites in abused pregnant patients are the breasts and genitals.

Abused pregnant women often suffer from low self-esteem, despair, anxiety, fear, withdrawal, post-traumatic stress disorder, passivity, learned helplessness, and depression and have high rates of attempted suicide.[67,71] Abused pregnant women may have vague physical symptoms, including headache, fatigue, insomnia, choking sensations, gastrointestinal complaints, pelvic pain, and backache. These symptoms may be manifestations of a deep depression or of a conversion reaction related to the adversity of the home environment.

Abused pregnant women do not believe that they have control over the health of their fetus. They hold a strong belief that chance is the major determinant in fetal outcome. This perception and the associated behavior (e.g., cigarette smoking, alcohol and drug abuse) are unlikely to change unless abused women leave their abusive situation. Only then will they be able to improve their sense of power and self-esteem and to make changes in their behavior that are in the best interest of the fetus.[67] Identification and appropriate referral are paramount in the management of an abused pregnant patient. Most abused patients will not volunteer information about domestic violence unless they are specifically asked. Cross-sectional survey data obtained from interviews with 261 pregnant women in 1991 suggest that 33.3% of women will report abuse when asked. They are more likely to disclose such information to another woman or medical personnel of either sex who are sympathetic and offer protection, support, and access to help.[71] Fear that an abused woman will be offended by direct questioning is unfounded.[67] It is important to include direct queries about abuse or risk of abuse in taking a history from a patient in the absence of her partner. Direct questioning may take the form of the following:

How do you and your partner resolve disagreements?

Have you been hit or hurt by anyone in the last year?[67]

Are you concerned for your safety or the safety of your children?

Many women come to the ED with similar problems and are victims of violence. Could this be what happened to you today?[71]

If a pregnant patient is found to be at high risk and living in dangerous circumstances, it is prudent to arrange for immediate shelter or hospital admission. All patients identified as victims of abuse should be referred to social services, community support groups, and, if appropriate, substance abuse programs. Referral for psychiatric and high-risk obstetric consultations may be indicated as well.

MANAGEMENT

Perspective

The assessment and care of pregnant patients require specialized equipment and access to specific ancillary tests. Basic equipment for the management of all obstetric and gynecologic emergencies includes a variety of specula, a Doppler ultrasonographic device for fetal heart readings, and ultrasonography with a transabdominal probe. The specula should be available in at least four blade widths: extra narrow at 16 mm (e.g., Miltex Pederson), narrow at 22 mm (e.g., Miltex Pederson), regular at 25 mm (e.g., Pederson), and wide at 35 mm (e.g., Graves). Speculum blades are available in three lengths: small at 7.7 cm, medium at 10.2 cm, and large at 17.8 cm. The medium-length Pederson speculum provides adequate exposure for most women. Virginal or postmenopausal women may require a narrow or extra-narrow speculum with a 10.2-cm-long blade. Pelvic examination of obese patients or patients in whom the vaginal walls are loose and redundant may necessitate the use of a Graves speculum.

Appropriate diagnostic imaging (transabdominal and transvaginal sonography as well as color Doppler ultrasonography or impedance plethysmography) and laboratory testing (both quantitative and qualitative hCG testing) should be available at all times. Access to MRI should be available by prior arrangement if equipment is not on site. If ready access to a high-risk obstetric unit is not available, prearranged agreements for transport to specialized centers for high-risk obstetric patients and neonates should be in place.

Health Promotion and Disease and Injury Prevention in Pregnancy

After complications of pregnancy and comorbid conditions have been excluded, pregnant patients should initially be counseled, appropriately referred, and encouraged to participate in regular prenatal care. The proportion of American women beginning prenatal care during the first trimester has consistently increased since the early 1990s, with a rate of 84% reported in 2004.[1] Although the time for prenatal counseling is limited in the ED, such counseling can have a positive impact on both fetal and maternal health. The following discussion is not inclusive of all prenatal issues; however, it does outline some of the most commonly identified risks and patient concerns along with the appropriate advice that should be given.

Use of Seat Belts, Helmets, and Air Bags

The use of three-point seat belt restraints should be emphasized. There is no evidence that these restraints will increase the chance of fetal injury. The proper use of seat belts is a good predictor of a favorable maternal and fetal outcome in the case of vehicular trauma.[72] The lap belt should be snugly and comfortably placed low across the maternal pelvis, below the uterine corpus and fundus and across the thighs, with the shoulder belt positioned between the breasts and no excessive slack allowed anywhere in the belt.[73] The National Highway Traffic Safety Administration does not consider pregnancy to be an indication for the deactivation of air bags and recommends the combined use of seat belts and air bags.[74] All patients should be encouraged to wear helmets when riding a bicycle or a motorcycle, whether voluntarily or in compliance with the law; these modes of transportation are ill-advised during pregnancy and certainly inappropriate during the third trimester.

Safe infant feeding should be reinforced. It is inappropriate and unsafe to breast-feed in a moving vehicle. Similarly, it is unsafe to remove the child from the restraining device to bottle-feed while in a moving vehicle.

Sexual Intercourse during Pregnancy

Sexual intercourse is considered harmless for a normal pregnant female. Most texts recommend abstinence during the last 4 weeks of pregnancy or when abortion or preterm labor is threatened.

Safety of Douching during Pregnancy

Guidelines should be adhered to for the proper use of douches during pregnancy. Hand-held bulb syringes are prohibited because of the risk of air embolism. The height of the douche bag should

www.ketabpezeshki.com 66485457-66963820

be limited to 2 feet or less above the level of the hips to prevent high fluid pressure. The nozzle should not be inserted more than 8 cm into the vagina.

Travel Restrictions during Pregnancy

Current ACOG guidelines suggest that occasional travel is generally safe for pregnant patients in the absence of maternal or obstetric complications (i.e., preeclampsia, intrauterine growth restriction).[75] Most airlines allow women with normal pregnancies to travel up to 35 or 37 weeks. It should be emphasized to the pregnant traveler that she should walk about at least every 2 hours to minimize the risk for thromboembolism. Other concerns, such as noise, vibration, and cosmic radiation, are a negligible risk for the occasional pregnant air traveler.[75] However, pregnant airline employees or frequent flyers should consult a physician during pregnancy because of their increased exposure to these potential risks.

Immunization during Pregnancy

The Advisory Committee on Immunization Practices posts guidelines for immunization during pregnancy on the website of the Centers for Disease Control and Prevention (CDC). Immunization of pregnant women should be guided by risk-versus-benefit logic. Relative indications for vaccination follow three guiding principles: (1) the risk of exposure is high, (2) the infection could cause harm to the mother or infant, and (3) the vaccine is unlikely to cause harm. Live virus vaccines generally are contraindicated during pregnancy because of the theoretic risk of transmission of the virus to the fetus. If a pregnant patient has received a live virus vaccine in the 3 months before the pregnancy, she should be referred for counseling on the potential risks to the fetus.[76] The annual influenza vaccination is recommended by the CDC for pregnant patients as there is increased risk of acquiring the illness while pregnant and higher morbidity and mortality rates due to influenza.[77] Comprehensive and specific guidelines for each vaccine are updated and posted on the CDC website (www.cdc.gov/vaccines/pubs/ACIP-list.htm).

Importance of Regular Appropriate Exercise

Suitable regular exercise should be encouraged during pregnancy because it helps prevent venous stasis and thromboembolic disease, maintain regular bowel movements, improve posture and perineal muscle strength, and regulate weight gain. Sedentary lifestyles and work activities that are performed predominantly in the sitting position should be discouraged. The ACOG recommends that healthy pregnant women without medical or obstetric complications adhere to the standard of exercise for nonpregnant patients recommended by the CDC and the American College of Sports Medicine. The standard aimed at improving health and well-being includes an accumulation of 30 minutes or more of moderate activity daily. Pregnant patients with comorbid conditions require exercise also and should engage in regular exercise with close medical supervision.

Patients should be encouraged to strengthen the abdominal muscles; to stretch the lower part of the back; to balance pectoralis muscle strength with that of the trapezius, rhomboids, and latissimus dorsi; to strengthen the cervical spine flexors; and to perform regular pelvic tilt exercises in all positions to correct the postural imbalance of pregnancy, to relieve discomfort, and to reduce the frequency of stress incontinence. Women with previous exercise regimens should be encouraged to continue these throughout their pregnancy and may even include high-impact activities such as jogging in the absence of medical or obstetric complications. Moderate exercise should be performed on most if not all days of the week, with special attention paid to adequate hydration and nutrition. Women starting an exercise regimen during pregnancy should generally wait until the second trimester and subsequently follow a graduated prescription for the amount and intensity of exercise throughout the remainder of their pregnancy.[78] Aggressive abdominal exercises are discouraged after 12 weeks of gestation because they may exacerbate the development of diastasis recti. Moderate regular abdominal strengthening exercises will minimize the lordosis of pregnancy.

Diet, Vitamin Supplementation, and Weight Gain Recommendations

It is not recommended that pregnant patients take routine multivitamin supplementation; however, iron supplements may be recommended, especially during the latter half of pregnancy. It also is recommended that 1 mg of folic acid be taken daily, beginning 1 month before conception and continuing throughout the first trimester to reduce the risk for neural tube defects.

Obesity is an increasingly common concern that is complicating pregnancies worldwide. Estimates of obesity in pregnant women in the United States range from 18 to 38%.[79] Obesity has been shown to complicate pregnancy by increasing rates of gestational diabetes, pregnancy-induced hypertension, preeclampsia, and venous thromboembolism.[79]

The ACOG recommends an average weight gain for pregnant women of between 10 and 12 kg.[80] The normal physiologic changes of pregnancy account for approximately 9 kg. The remainder is maternal fat storage.[81] The Institute of Medicine makes weight gain recommendations according to prepregnancy weight: underweight women (13-18 kg), normal-weight women (11-16 kg), overweight women (7-11 kg), and obese women (5-9 kg).[82]

Appropriate Management of Pregnant Patients with Substance Abuse Problems

The risks of smoking, illicit drug use, and excessive alcohol consumption during pregnancy are widely known to the lay public; however, despite warnings, some pregnant women continue to smoke and imbibe excessively. Cigarette smoking during pregnancy has declined steadily since 1989, to 18% in 2002-2003 and 16% in 2007-2008.[83] Nonetheless, tobacco use by pregnant mothers aged 18 to 25 years continues to be high, with a reported rate of 22% in 2008. The U.S. Department of Health and Human Services Substance Abuse and Mental Health Services Administration concluded from its National Household Survey on Drug Abuse (2007-2008 database) that among women 15 to 44 years of age who were currently pregnant, 5% used one or more illicit drugs in the past month, 4.5% engaged in "binge" alcohol use, and slightly less than 20% were past-month cigarette smokers. *Binge drinking* was defined as drinking five or more drinks on the same day at least once during the previous 30 days. In comparison with a nonpregnant cohort, women who abuse substances reported curtailing their use during pregnancy and resuming use postpartum. Substance abuse during pregnancy was more frequent in unmarried women without a high-school education. The prevalence decreased as the amount of adult education increased. The prevalence of drug abuse during the last month of pregnancy showed no difference between Hispanic and white pregnant women. Drug abuse during pregnancy was significantly more common among black than among Hispanic patients.[83]

www.ketabpezeshki.com 66485457-66963820

KEY CONCEPTS

- Female patients of childbearing age should be assumed to be pregnant; 11.5% of women with abdominal pain or vaginal bleeding have a positive result on pregnancy testing even when they have stated that there is "no chance" they are pregnant.
- Accurate vital signs are best obtained with pregnant patients in the left lateral decubitus position and should include measurement of the fetal heart rate, if it is obtainable.
- ELISA is the state-of-the-art urine pregnancy test. It offers excellent user convenience and has a sensitivity for levels of hCG between 25 and 50 mIU/mL.
- The decision to perform diagnostic imaging investigations in a pregnant patient must take into consideration the risk to the developing fetus from radiation exposure, the inherent risk of such investigations for the mother, and the risk to the mother and the fetus associated with missing the diagnosis because of reluctance to use available imaging techniques.
- In general, a pregnant patient should be treated and assessed in the same way as all other patients are. However, the normal physiologic changes of pregnancy may mask or unmask underlying medical conditions.
- The ED encounter is an opportunity to reinforce or to provide primary education and advice on health promotion and disease and injury prevention in pregnancy.

ACKNOWLEDGMENT

The authors would like to acknowledge with permission granted that Michael J. Romano contributed to the formatting, updating of the literature, and first draft of the revisions for this version of the chapter. None of the authors has any financial conflicts of interest pertaining to the subject addressed in this chapter.

Chapter 178

Acute Complications of Pregnancy

Debra E. Houry and Bisan A. Salhi

PERSPECTIVE

Acute complications of pregnancy can appear in all trimesters and pose challenges in diagnosis and management for the emergency physician. Life-threatening disorders, such as ectopic pregnancy in early pregnancy, pregnancy-induced hypertension in mid to late pregnancy, and abruptio placentae in late pregnancy, are relatively common. Clinicians must consider the signs and symptoms, stage of pregnancy, and hemodynamic stability of the patient in developing diagnostic and treatment strategies.

PROBLEMS IN EARLY PREGNANCY

Miscarriage

Perspective

Miscarriage, the most common serious complication of pregnancy, is defined as the spontaneous termination of pregnancy before 20 weeks of gestation. Fetal demise after 20 weeks of gestation or when the fetus is more than 500 g is considered premature birth. Loss of early pregnancy, defined as detection of human chorionic gonadotropin (hCG) within 6 weeks of the last normal menstrual period, occurs in approximately 20 to 30% of pregnancies.[1-3] Embryonic and fetal loss after implantation occurs in up to one third of detectable pregnancies. The risk of miscarriage rises with increasing maternal age (fivefold increase in those older than 40 years compared with those 25 to 29 years), increasing paternal age, alcohol use, increased parity, history of prior miscarriage, poorly controlled diabetes mellitus and thyroid disease, low pre-pregnancy body mass index, maternal stress, and history of vaginal bleeding.[4-6] Approximately 80% of miscarriages occur during the first trimester; the rest occur before 20 weeks of gestation.

Threatened or actual miscarriage is a common presentation of patients in the emergency department (ED). Approximately one fourth of clinically pregnant patients experience some bleeding. It is estimated that up to 50% of all women who have bleeding during early pregnancy miscarry, although the risk is probably higher in the ED population.[7,8] Patients who have a viable fetus visualized on ultrasound examination have a much lower risk of miscarriage (3-6%), although vaginal bleeding is a high-risk indicator, even when a viable fetus is present.[9] Those with a history of bleeding who do not miscarry may have otherwise normal pregnancies, although they have an approximately twofold increased risk of premature birth and low-birth-weight infants.[10]

Principles of Disease

Pathophysiology. The majority of miscarriages are due to either uterine malformations or chromosomal abnormalities, which account for the majority of miscarriages that occur within 10 weeks of gestation.[6] In some cases the ovum never develops (anembryonic gestation). In the majority of early miscarriages, fetal death precedes clinical miscarriage, often by several weeks. Although clinical symptoms of miscarriages are most common between 8 and 12 weeks of gestation, sonographic evidence in most cases demonstrates death before 8 weeks; if fetal viability can be demonstrated by heart activity and a normal sonogram, the subsequent risk of fetal loss decreases significantly.

Maternal factors that increase the risk of miscarriage include congenital anatomic defects, uterine scarring, leiomyomas, and cervical incompetence. Other conditions associated with increased miscarriage rates include toxins (e.g., alcohol, tobacco, and cocaine), autoimmune factors, endocrine disorders, including luteal phase defects, and occasional maternal infections.[2-5]

Terminology. Miscarriage can be broadly categorized into three categories. The first is a *threatened miscarriage,* in which the patient presents with vaginal bleeding but is found to have a closed internal cervical os. The risk of miscarriage in this population is estimated at 35 to 50%, depending on the patient's risk factors and severity of symptoms.[11] If the internal cervical os is open, the miscarriage is considered *inevitable.* If products of conception are present at the cervical os or in the vaginal canal, the miscarriage is termed *incomplete,* the second classification of miscarriage. The third classification is a *completed* miscarriage, which occurs when the uterus has expelled all fetal and placental material, the cervix is closed, and the uterus is contracted. Establishment of the diagnosis of completed miscarriage is difficult in the ED. A gestational sac should be visualized for diagnosis because the cervix may close after an episode of heavy bleeding and clot passage without or after only partial expulsion of the products of conception. Unless an intact gestation is passed and recognized, completed miscarriage should be diagnosed only after dilation and curettage (D&C) with pathologic confirmation of gestational products, demonstration by sonography of an empty uterus with a prior known intrauterine pregnancy (IUP), or reversion to a "negative" pregnancy test result. This may take up to several weeks after the initial presentation.

Missed abortion is a relatively obsolete term referring to clinical failure of uterine growth over time. The terms *anembryonic gestation* (when no fetus is seen), *first-* or *second-trimester fetal death* (failure to see fetal heart activity in a fetus with at least a 5-mm crown-rump length), and *delayed miscarriage* are more appropriate.

www.ketabpezeshki.com 66485457-66963820

Clinical Features

Patient history should include the estimated length of the gestation; time since last menstrual period; symptoms of pregnancy (including evolution or loss of pregnancy symptoms); degree of bleeding; duration of bleeding; presence of cramps, pain, or fever; and attempts by the patient to induce miscarriage. Whereas the history is important, it is not helpful in the classification of the type of miscarriage. In addition, the severity of symptoms does not correlate well with the risk of miscarriage, although cramping and passage of clots are thought more likely to occur as the miscarriage becomes inevitable.

The assessment of the patient who experiences first-trimester vaginal bleeding includes a careful abdominal examination to evaluate for tenderness or peritoneal irritation from a potential ectopic pregnancy as well as to determine uterine size (the uterus should not be palpable abdominally). Pelvic examination should be performed to evaluate whether the cervix is closed or open, to look for clots or the products of conception, and to determine the degree of vaginal bleeding as well as uterine size and tenderness. The cervix should be gently probed with a ring forceps (not a cotton-tipped applicator) to determine whether the internal os (1.5 cm deep to the external os) is open or closed. This is unnecessary in the patient who has a clearly open os or visible products of conception but can be safely performed during the first trimester as long as the forceps are used gently and do not penetrate the cervix more than 2 or 3 cm. In the patient with second-trimester bleeding, probing should not be done because the uterus is more vascular and the organized placenta may overlie the cervical os. Parous women normally have an open or lax external os, a finding of no significance. The adnexa may be enlarged, often unilaterally, either because the corpus luteum is cystic or because the pregnancy is ectopic. Significant adnexal or uterine tenderness should always raise the possibility of an ectopic pregnancy. Much less commonly, pelvic infection can cause uterine and adnexal tenderness during early pregnancy.

Any tissue that is passed should be suspended in saline or tap water (or viewed under low-power microscopy) to differentiate sloughing endometrium and organized clot from chorionic villi, which form fronds and appear feathery in the saline suspension. Except in the rare instance of heterotopic pregnancy (combined intrauterine and ectopic pregnancies), this reliably excludes ectopic pregnancy. Passage of tissue called the *decidual cast* in ectopic pregnancy can easily be confused with intrauterine miscarriage if the physician does not confirm the absence of chorionic villi in the tissue.[12]

Diagnostic Strategies

A hemoglobin level is useful to provide a baseline measurement and to evaluate the degree of blood loss in women whose bleeding persists. In addition, an Rh type should be obtained. Ultrasonography is the primary means of evaluating the health of the fetus as well as its location (Table 178-1). Because historical and clinical estimations of gestational age are often inaccurate, ultrasonography is useful to provide an accurate measure of fetal age and viability (Box 178-1).

In the stable patient with threatened miscarriage, expectant management may be sufficient to determine when intervention is needed as long as ectopic pregnancy has been excluded. Serial quantitative hCG levels are used to assess the health of the fetus if sonographic findings are indeterminate or if the gestational age is less than 6 or 7 weeks. The sonographic "discriminatory zone" is defined as the quantitative hCG level at which a normally developing IUP should reliably be seen. This is considered to be 6500 mIU/mL for transabdominal ultrasonography and 1000 to 2000 mIU/mL for transvaginal ultrasonography.[13] Ultrasonography can be performed or repeated when hCG levels rise to 1500 to 3000 mIU/mL. If hCG levels are flat or decline or if sonographic criteria for fetal demise are demonstrated (see Box 178-1), the patient should be referred to an obstetrician for follow-up to ensure miscarriage completion and to rule out subsequent complications.

Table 178-1 Landmarks for Gestational Age and β-hCG Level by Transvaginal Ultrasonography

FINDING	WEEKS FROM LMP	β-hCG (mIU/mL)
Gestational sac (25 mm)	5	1000
Discriminatory zone	5-6	1000-2000
Yolk sac	6	2500
Upper discriminatory zone	6-7	3000
Fetal pole	7	5000
Fetal heart motion	6-7	7000

Modified from Ramsey E, Shilitto J: How early can fetal heart pulsations be detected reliably using modern ultrasound equipment? Ultrasound 16:193-195, 2008.
β-hCG, beta subunit of human chorionic gonadotropin; *LMP,* last menstrual period.

Box 178-1 Sonographic Criteria for Abnormal Pregnancy with Transvaginal Ultrasonography

No gestational sac at β-hCG level of 3000 mIU/mL
No yolk sac with gestational sac of 13 mm (or at 32 days since last menstrual period)
5-mm crown-rump length with no fetal heart tones
No fetus with gestational sac of 25 mm mean diameter
No fetal heart tones after 10-12 weeks' gestational age

Adapted from Dart RG: Role of pelvic ultrasonography in evaluation of symptomatic first-trimester pregnancy. Ann Emerg Med 33:310. 1999.
β-hCG, beta subunit of human chorionic gonadotropin.

Differential Considerations

Ectopic pregnancy can masquerade as a threatened miscarriage in the early stages of pregnancy and should always be considered in the differential diagnosis. Even in the patient with painless vaginal bleeding, the diagnosis of ectopic pregnancy must be considered.[12] Thus early ultrasonography is imperative to locate the pregnancy in the patient who has bleeding or pain.

Other diagnoses should also be considered. A small amount of bleeding occurs at the time of implantation of the blastocyst into the endometrium and occasionally at the time of the first missed menses. Molar pregnancy is also characterized by vaginal bleeding, usually during the late first trimester or the second trimester. This condition can be identified by ultrasonography. Cervical and vaginal lesions can also cause local bleeding and can usually be seen on vaginal inspection.

Management

After assessment of hemodynamic status and management of blood loss, a patient with a threatened miscarriage requires very little specific medical treatment. Anti-D immune globulin should be administered if the patient is Rh negative (unless the father is also known to be Rh negative). A 50-μg dose is used during the first trimester and a full 300-μg dose after the first trimester.[14] Once ectopic pregnancy has been excluded, ultrasonography can be scheduled more routinely at a later time in the patient without significant pain as long as the patient is aware that the potential for ectopic pregnancy exists until it is excluded by identification

www.ketabpezeshki.com 66485457-66963820

of an IUP. In the patient who is planning pregnancy termination, prompt referral should be encouraged and chorionic villi confirmed at the time of uterine evacuation.

Unless an IUP is diagnosed, the patient with threatened miscarriage should be given careful instructions on discharge to return if she has signs of hemodynamic instability, significant pain, or other symptoms that might indicate ectopic pregnancy (so-called ectopic precautions). In conjunction with gynecologic colleagues, an ED protocol is useful to determine when follow-up sonographic evaluation and serial hCG measurements should be obtained as ultrasonography can be an inaccurate diagnostic tool if the hCG level is significantly low, if vaginal bleeding is significant, or if ultrasonographic findings do not include a fetal pole or yolk sac.[15]

Although 50% or more of women with threatened miscarriage who are seen in the ED ultimately miscarry, treatment to "prevent" miscarriage is not useful as most fetuses can be shown to be nonviable 1 to 2 weeks before symptoms occur. In most cases, spontaneous miscarriage is the body's natural method of expelling an abnormal or undeveloped (blighted) pregnancy. Thus a major goal of early management should be patient education and support. Patients should be advised that moderate daily activities do not affect the pregnancy. Tampons, intercourse, and other activities that might induce uterine infection should be avoided as long as the patient is bleeding, and she should return immediately for fever, abdominal pain, or a significant increase in bleeding. Cramping from a known IUP can be safely treated with oral synthetic narcotics, if needed. If the patient passes tissue, it should be brought to a provider to be examined for products of conception because differentiation of fetal parts or villi from decidual slough or casts is difficult.

Patient counseling is paramount with threatened miscarriage.[16,17] Determination of fetal viability can be helpful in either reassuring the mother or preparing her for probable fetal loss. Miscarriages are associated with a significant grieving process, which is frequently more difficult because early pregnancy is unannounced and early fetal death is not publicly recognized. Because many women consider that small falls, injuries, or stress during the first trimester can precipitate miscarriage, patients should be reassured that they have done nothing to cause miscarriage. It is important to make them aware that miscarriage is common, grieving is normal, and counseling may be beneficial.[18,19] A follow-up appointment should be scheduled after miscarriage to support the patient in resolving such issues.

Treatment of the patient with incomplete miscarriage includes expectant management, medical management with misoprostol, or surgical evacuation.[18,20] When the miscarriage is incomplete, the uterus may be unable to contract adequately to limit bleeding from the implantation site. Bleeding may be brisk, and gentle removal of fetal tissue from the cervical os with ring forceps during the pelvic examination often slows bleeding considerably.

Management of patients with presumed completed miscarriage is more complicated. If the patient brings tissue with her, this should be sent to the pathology department for evaluation. Unless an intact gestational sac or fetus is visualized, it is rarely clear clinically whether miscarriage is "complete." Studies have shown that in women with a history consistent with miscarriage who have minimal remaining intrauterine tissue as determined by ultrasonography, expectant management is safe, but only if ectopic pregnancy can be excluded.[20] If endometrial tissue is not seen with ultrasonography, bleeding is mild, and gestational age is less than 8 weeks, curettage is frequently unnecessary and the patient can be safely observed by a gynecologist for serial hormonal assays. Up to 80% of women with first-trimester miscarriage complete the miscarriage without intervention.[21] However, the need for later visits and procedures may be decreased by uterine curettage, particularly if the fetal pole or a gestational sac is visible on the sonogram at the time of evaluation.[20] Medical management with misoprostol instead of D&C is also an option and has a success rate of up to 96%.[18,22,23] The patient should be instructed to return if uncontrolled bleeding, severe pain or cramping, fever, or tissue passage occurs. Follow-up is recommended in 1 or 2 weeks to ensure that the miscarriage is complete.

After miscarriage, the patient should be advised that fetal loss, even during the first trimester, can cause significant psychological stress.[16] Follow-up in 1 or 2 weeks with a gynecologist should be provided. Some physicians prescribe antibiotics after D&C (usually doxycycline or metronidazole), particularly in populations of patients at high risk for genital tract infections. Ergonovine or methylergonovine (0.2 mg orally twice daily) can be used to stimulate uterine involution. The patient should be advised to return if signs of infection (fever or uterine tenderness) occur, if bleeding resumes, or if further tissue is passed.

Ectopic Pregnancy

Perspective

Ectopic pregnancy, or pregnancy implanted outside the uterus, is an increasingly frequent problem that poses a major health risk to women during the childbearing years. It is the third leading cause of maternal death, responsible for 6% of maternal mortality.[24] The incidence of ectopic pregnancy has risen steadily during several decades and now accounts for approximately 2% of all pregnancies. Although the incidence of ectopic pregnancy is highest in women aged 25 to 34 years, the rate is highest among older women and women belonging to minority groups. Simultaneous intrauterine and extrauterine gestations (heterotopic pregnancy) have historically been rare, occurring in approximately 1 in 4000 pregnancies; more recently, women who have undergone assisted reproduction techniques with embryo transfer have demonstrated a risk of one of the pregnancies being ectopic of 4% or greater. The incidence of ectopic pregnancy among women presenting to the ED with vaginal bleeding or pain in the first trimester is consistently approximately 10% in several series.[25,26]

Principles of Disease

Implantation of the fertilized ovum occurs approximately 8 or 9 days after ovulation. Risk factors for an abnormal site of implantation include prior tubal infection (50% of cases), anatomic abnormalities of the fallopian tubes, and abnormal endometrium (host factors). These result in failure of the embryo to implant in the endometrium. The risk of ectopic pregnancy increases approximately threefold after a patient has had pelvic inflammatory disease (PID). In recent studies, one fourth of patients with ectopic pregnancies have had tubal surgery, including tubal sterilization or removal of ectopic pregnancy.[27] If the patient is currently using an intrauterine device, increased risk can occur from complicating PID or from failure of the intrauterine device to prevent pregnancy while preventing endometrial implantation. All forms of contraception except the intrauterine device and tubal sterilization decrease the incidence of ectopic pregnancy. After an ectopic pregnancy, the risk of a subsequent ectopic pregnancy was 22% in one series of women trying to conceive again (Box 178-2).[28]

When abnormal implantation occurs in the fallopian tubes, on the ovaries, or in the cervix, the pregnancy usually grows at a less than normal rate, which can result in abnormally low or declining hCG production. Blood leaks intermittently through the tubal wall or out the fimbrial ends, with spillage into the peritoneal cavity. Bleeding and other symptoms are usually intermittent. Three outcomes are possible: spontaneous involution of the pregnancy, tubal abortion into the peritoneal cavity or vagina, or rupture of the pregnancy with internal or vaginal bleeding.

www.ketabpezeshki.com 66485457-66963820

Box 178-2 Risk Factors for Ectopic Pregnancy

Tubal surgery (for tubal sterilization or ectopic pregnancy)
Pelvic inflammatory disease
Smoking
Advanced age
Prior spontaneous abortion
Medically induced abortion
History of infertility
Intrauterine device

Modified from Bouyer J, et al: Risk factors for ectopic pregnancy: A comprehensive analysis based on a large case-control, population-based study in France. Am J Epidemiol 157:185, 2003.

Implantation in the uterine horn (cornual pregnancy) is particularly dangerous because the growing embryo can use the myometrial blood supply to grow larger (10-14 weeks of gestation) before rupture occurs.

Clinical Features

The classic clinical picture of ectopic pregnancy is a history of delayed menses, followed by abdominal pain and vaginal bleeding in a patient with known risk factors. Unfortunately, this history is neither sensitive nor specific. Risk factors for ectopic pregnancy are absent in almost half of patients. Fifteen percent to 20% of patients with symptomatic ectopic pregnancy have not missed a menstrual period, and occasionally the patient has no history of vaginal bleeding. Abdominal pain is most commonly severe, peritoneal in nature, and constant. Shoulder pain implies free fluid in the peritoneal cavity and is suggestive of an ectopic pregnancy with significant hemorrhage. The pain of ectopic pregnancy can also be crampy, intermittent, or even absent.[12,29]

The physical examination findings in ectopic pregnancy are likewise variable. Vaginal bleeding, uterine or adnexal tenderness, or both in the patient with a positive pregnancy test result should trigger consideration of ectopic pregnancy. Tachycardia is not always present, even with significant hemoperitoneum; hemoglobin level is usually normal, and hypotension may be seen.[29] The presence of peritoneal signs, cervical motion tenderness, or lateral or bilateral abdominal or pelvic tenderness indicates increased likelihood of an ectopic pregnancy. If significant peritoneal irritation is present, pain can preclude accurate bimanual examination. Adnexal masses are felt in only 10 to 20% of patients with ectopic pregnancy.[12,29] Vaginal bleeding is often mild. Heavy bleeding with clots or tissue usually suggests a threatened or incomplete miscarriage, although the patient with an ectopic pregnancy who has decreasing hormonal levels may experience endometrial sloughing, which can be mistaken for passage of fetal tissue. Passed tissue should be examined, as with cases of miscarriage, in tap water or saline (or under low-power microscopy). Unless fetal parts or chorionic villi are seen, ectopic pregnancy should not be excluded in the patient with bleeding or passage of "tissue."

Diagnostic Strategies

Because both the history and the physical examination of the patient with ectopic pregnancy are insensitive and nonspecific, ancillary studies are essential to locate the pregnancy in any patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result. Technologic advances have allowed accurate detection or exclusion of ectopic pregnancy in the assessment of the woman with first-trimester vaginal bleeding or pelvic pain. Ultrasonography and hormonal assays are the most commonly used ancillary tests. Laparoscopy may be the most efficient diagnostic tool in some instances.

Box 178-3 Sonographic Findings in the Patient with Suspected Ectopic Pregnancy

Diagnostic of Intrauterine Pregnancy
"Double" gestational sac
Intrauterine fetal pole or yolk sac
Intrauterine fetal heart activity

Diagnostic of Ectopic Gestation
Pregnancy in fallopian tube (Fig. 178-1)
Ectopic fetal heart activity (Fig. 178-2)
Ectopic fetal pole

Suggestive of Ectopic Gestation
Moderate or large cul-de-sac fluid without intrauterine pregnancy
Adnexal mass without intrauterine pregnancy*

Indeterminate
Empty uterus (Fig. 178-3)
Nonspecific fluid collections (Fig. 178-4)
Echogenic material
Abnormal sac (Fig. 178-5)
Single gestational sac

Modified from Dart RG: Role of pelvic ultrasonography in evaluation of symptomatic first-trimester pregnancy. Ann Emerg Med 33:310, 1999.
*Complex mass is the most suggestive of ectopic pregnancy, but a cyst can also be seen with ectopic pregnancy.

Figure 178-1. Pregnancy in the fallopian tube, diagnostic of an ectopic pregnancy. (Courtesy Mary Ann Edens, MD.)

Ultrasonography. Ultrasonography is the primary method used to locate early gestation, to establish gestational age, and to assess fetal viability. Transabdominal ultrasonography is most useful for identification of IUPs with fetal heart activity and exclusion of ectopic pregnancy (except in patients at high risk for heterotopic pregnancy because of infertility procedures).[13] Transvaginal ultrasonography is more sensitive, recognizes IUP earlier than transabdominal ultrasonography does, and is diagnostic in up to 80% of stable patients presenting in the first trimester.[30]

Sonographic findings in the patient with suspected ectopic pregnancy are listed in Box 178-3 and illustrated in Figures 178-1 to 178-5. In general, an indeterminate ultrasound study usually does not result in a diagnosis of normal pregnancy; one series of more than 1000 pelvic ultrasound examinations reported that 53% of indeterminate ultrasound studies resulted in a diagnosis of embryonic demise, 15% were ectopic pregnancies, and only 29% had an IUP.[31] However, correlation of sonographic results with quantitative hCG measurements can add to the predictive value.[32] With hCG levels of less than 1000 mIU/mL, the risk of

Figure 178-5. Ultrasonography showing a gestational pseudosac. (Courtesy Mary Ann Edens, MD.)

ectopic pregnancy increases fourfold; ultrasonography is still diagnostic in a significant minority of patients (one third of patients with ectopic pregnancy), although the accuracy of sonographic findings may decrease.[31] Normal pregnancy is unlikely if no gestational sac is seen by transvaginal ultrasonography with an hCG level higher than 1000 to 2000 mIU/mL, depending on the institution's discriminatory zone, but the differential diagnosis includes both miscarriage and ectopic pregnancy. Unfortunately, levels of approximately 1500 mIU/mL develop in only approximately half of patients with ectopic pregnancies (see Table 178-1).[8,13]

Indeterminate sonograms, which demonstrate neither an IUP nor extrauterine findings suggestive of ectopic pregnancy, occur in approximately 20% of ED evaluations of women with first-trimester bleeding or pain. Ectopic pregnancy is more likely among this subgroup with indeterminate sonograms if the hCG level is less than 1000 mIU/mL and when the uterus is empty. Endometrial debris and fluid in the uterus do not exclude ectopic pregnancy.[33]

Use of bedside ultrasonography in the ED for the diagnosis of IUP and the exclusion of ectopic pregnancy has shown good sensitivity and negative predictive value in ruling out ectopic pregnancy, but it requires significant operator training.[34-38] In addition to operator-based limitations, it is also limited by device availability and quality within the ED.

Hormonal Assays. The quantitative hCG levels have two primary uses: serial levels can be used in the stable patient who can be observed as an outpatient, and a single level can be correlated with sonographic results for improved interpretation. Serum hCG

www.ketabpezeshki.com 66485457-66963820

levels normally double every 1.8 to 3 days for the first 6 or 7 weeks of pregnancy, beginning 8 or 9 days after ovulation. An initial quantitative level can be measured at the time of the ED visit, particularly if the sonogram is indeterminate or the gestational age is estimated as less than 6 weeks. A repeated level should be measured 48 to 72 hours later. Levels that fall or rise slowly are associated with abnormal pregnancy, either intrauterine or ectopic. Twenty-one percent of women with an ectopic pregnancy in one series had an initial rise in hCG at a rate consistent with an IUP.[36]

Single quantitative hCG levels can also be useful in conjunction with ultrasonography; normal IUPs should be visible transvaginally at 1000 to 2000 mIU/mL hCG or higher (see Table 178-1). A benign course for ectopic pregnancy cannot be assumed with low hCG levels; ruptured ectopic pregnancies requiring surgery have been reported with very low or absent levels of hCG.[39]

Serum progesterone levels have been studied as an additional or alternative marker to determine which patients need further evaluation and follow-up for possible ectopic pregnancy. Progesterone rises earlier than hCG in normal pregnancy and plateaus with levels higher than 20 ng/mL, so measurement of serial levels over time is not necessary. Levels below 5 ng/mL exclude viable IUP (with rare exceptions) and could be useful when hCG levels are low, ultrasonography is indeterminate, and the clinician is considering D&C or laparoscopy. The ability of a progesterone level to differentiate ectopic pregnancy from a failed IUP is limited, however, and it is not a standard tool for ED evaluation.

Other Ancillary Studies. Dilation and evacuation can be used in patients without a viable IUP or ectopic pregnancy on ultrasonography to differentiate intrauterine miscarriage from ectopic pregnancy. Identification of chorionic villi in endometrial samples is seen in approximately 70% of patients and excludes ectopic pregnancy (except in infertility patients). Identification of chorionic villi can be made even in 50% of women with an empty uterus on ultrasonography and limits the need for laparoscopy to exclude ectopic pregnancy in this population.[40]

Although it is invasive, laparoscopy is extremely accurate as a diagnostic (and therapeutic) procedure for possible ectopic pregnancy. It is the diagnostic treatment of choice in the unstable first-trimester patient with frank peritoneal signs and is also indicated in patients with significant peritoneal fluid or an ectopic gestation in the pelvic cavity. Medical alternatives for management of ectopic pregnancy have resulted in decreased indications in stable patients.[32,41]

Differential Considerations

The spectrum of clinical presentations in ectopic pregnancy is wide, so the differential diagnosis includes essentially all first-trimester complications. Threatened miscarriage, the most common alternative diagnosis, can be recognized by sonographic evidence of an IUP, either healthy or failed. Hypovolemia may be seen, particularly in incomplete miscarriage, but hypotension without significant vaginal hemorrhage is highly suggestive of ectopic pregnancy. Identification of fetal parts or chorionic villi in tissue expelled or obtained during D&C is useful to confirm a complication of IUP, although this is not sufficient to exclude ectopic pregnancy in the patient who has received infertility treatment and has an increased risk of heterotopic gestation.

A ruptured corpus luteum cyst should also be considered in the patient who has first-trimester bleeding associated with peritoneal pain or irritation. The corpus luteum normally supports the pregnancy during the first 7 or 8 weeks. Rupture causes pelvic pain and peritoneal irritation. Ultrasonography is helpful if it reveals an IUP (except in patients with in vitro fertilization). During early gestation, when ultrasonography is nondiagnostic, free fluid is usually visible by ultrasonography, and serial observation may be required (see Fig. 178-4). If the patient is unstable (especially if an IUP cannot be identified by ultrasonography), laparoscopy or, rarely, laparotomy may be required to differentiate between the two conditions.

Management

Classically, approximately 20% of women with ectopic pregnancies manifest signs and symptoms warranting immediate intervention.[41] This includes patients with significant hypovolemia, large amounts of peritoneal fluid, or an open cervical os. For patients with significant signs of hypovolemia, rapid volume resuscitation should be instituted with intravenous fluids and blood products as necessary, and a baseline hemoglobin level and type and crossmatch should be obtained. A D&C or evacuation procedure with examination of endometrial contents for products of conception can be performed urgently in the unstable patient with an open cervical os.

If the patient remains unstable, immediate surgery is warranted. Laparoscopy may be indicated for patients who stabilize with treatment or for those who are hemodynamically stable but exhibit significant peritoneal signs. One study reported that identification of free fluid in Morison's pouch on bedside ultrasonography predicted the need for operative intervention in the majority of cases in patients with suspected ectopic pregnancies.[26] All patients with ectopic pregnancy who are Rh negative should be given Rh immune globulin 50 μg intramuscularly, unless the father is known to be Rh negative.

The majority of patients who seek treatment for bleeding or pain during the first trimester of pregnancy are stable. In such patients, the goal should be to exclude ectopic pregnancy in a timely manner. In the patient with significant pain by history or examination or significant risk factors for ectopic pregnancy, ultrasonography should be performed before discharge. If the results are indeterminate, a quantitative hCG level may be helpful in determining the patient's risk for ectopic pregnancy.

In low-risk patients with only minor symptoms or bleeding, ectopic pregnancy is still a possibility. Two general outpatient approaches can be considered. In most institutions, ultrasonography is the initial screening tool (Fig. 178-6). If an IUP is not seen, quantitative hCG levels help stratify patients by risk. In all cases, if the patient is discharged, careful instructions are given for symptoms that would require her earlier return (ectopic precautions).

An alternative strategy uses hCG levels first. However, waiting times for the serum assay can increase ED length of stay. In addition, ultrasonography is usually diagnostic of IUP or ectopic pregnancy, even if the hCG level is less than 1000 mIU/mL.[29,30] In most hands, the initial sonogram provides more rapid and accurate information.

A significant minority of patients have indeterminate sonographic results and hCG levels below 1000 mIU/mL. When the hCG levels never rise to the discriminatory zone, the differential diagnosis includes intrauterine fetal demise and ectopic pregnancy. Early D&C with identification of products of conception can be useful in the patient with nonrising hCG levels to detect chorionic villi and to confirm a failed IUP or to strongly suggest ectopic pregnancy.[40] Alternatively, hCG levels can be followed until they reach zero, particularly if initial levels are low.

Although laparotomy may be required for patients who have ectopic pregnancies, an increasing number of surgeries are being performed through the laparoscope. Salpingostomy is preferred to salpingectomy if the patient is stable and the procedure is technically feasible. Overall, the advent of transvaginal ultrasonography has resulted in a decreased number of surgeries and a trend toward nonoperative management.[42]

Medical management has become standard in many areas for the stable patient with minimal symptoms and is cost-effective

www.ketabpezeshki.com 66485457-66963820

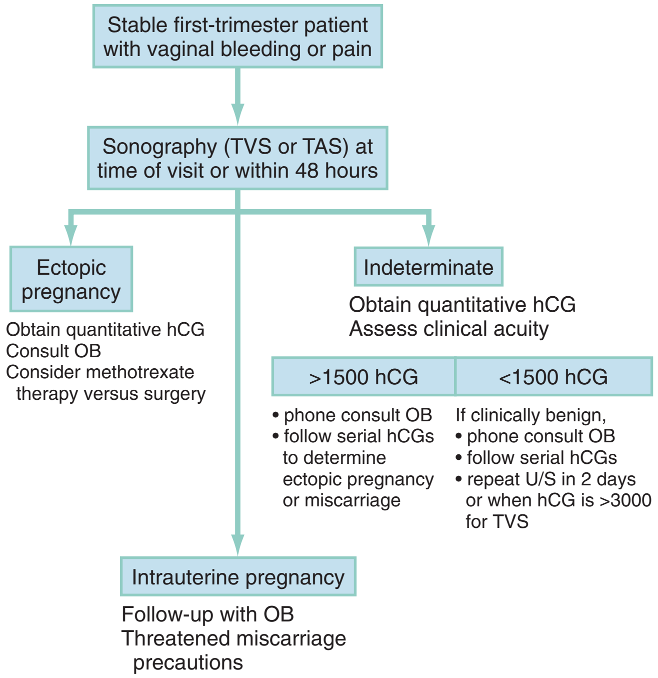

Figure 178-6. Management of vaginal bleeding or pain in the stable first-trimester pregnant patient. *hCG,* human chorionic gonadotropin; *OB,* obstetrics specialist; *TAS,* transabdominal sonography; *TVS,* transvaginal sonography; *U/S,* ultrasonography.

when subsequent fertility is being considered.[41] Methotrexate is the drug most commonly used to treat early ectopic pregnancy. It causes destruction of rapidly dividing fetal cells and involution of the pregnancy. Medical treatment is most often used for patients who are hemodynamically stable with a tubal mass smaller than 3.5 cm in diameter, no fetal cardiac activity, and no sonographic evidence of rupture. Although there is no agreed on cutoff for single-dose methotrexate, a systematic review found that patients with an hCG level above 5000 mIU/mL had an increased failure rate.[43] Medical therapies are associated with an 85 to 93% success rate, with no significant difference between single- and multiple-dose protocols.[44] Pelvic pain is common (60%) in patients receiving methotrexate, even when it is used successfully.[45] Indications of methotrexate failure and need for rescue surgery include decreasing hemoglobin levels, significant pelvic fluid, and unstable vital signs. All patients receiving methotrexate require close follow-up until the hCG level reaches zero, which may take 2 or 3 months.

Molar Pregnancy

Molar pregnancy, also known as gestational trophoblastic disease, comprises a spectrum of diseases characterized by disordered proliferation of chorionic villi. In the absence of fetal tissue, the pregnancy is termed a *complete hydatidiform mole*. More rarely, if fetal tissue is present and trophoblastic hyperplasia is focal, it is called an *incomplete mole*. In approximately 19% of molar pregnancies, neoplastic gestational disease develops, with persistence of molar tissue after the pregnancy has been evacuated.[46,47] Metastatic disease can develop, requiring chemotherapy and intensive oncologic management.

Early molar pregnancy is usually not clinically apparent. The most well described risk factor for development of a molar pregnancy is extremes of maternal age.[48] Many patients present with abdominal pain, nausea and vomiting, or vaginal bleeding, and it may be difficult to differentiate these patients from those with threatened miscarriage or ectopic pregnancy by historical features alone.[49] Patients sometimes seek treatment for apparent persistent hyperemesis gravidarum from high circulating levels of hCG, bleeding or intermittent bloody discharge, or respiratory distress; failure to hear fetal heart tones during the second trimester is the usual initial clue to diagnosis.[50,51] If molar pregnancy spontaneously aborts, it is usually in the second trimester (before 20 weeks), and the patient or physician may note passage of grape-like hydatid vesicles. Uterine size is larger than expected by date (by more than 4 weeks) in approximately 30 to 40% of patients. Theca lutein cysts may be present on the ovaries as a result of excessive hormonal stimulation, and torsion of affected ovaries can be seen.[50,51]

The diagnosis of hydatidiform mole is based on the characteristic sonographic appearance of hydropic vesicles within the uterus, described as a "snowstorm" appearance (Fig. 178-7). Alternatively, cystic changes are seen in partial molar pregnancies. In some cases, partial molar pregnancy is detected only on pathologic examination of abortion specimens.[52] Complications of molar pregnancy include preeclampsia or eclampsia (which can develop before 24 weeks of gestation), pulmonary embolization of trophoblastic cells, hyperemesis gravidarum, and significant uterine bleeding, either acute or chronic. Ultrasonography usually provides the diagnosis of complete molar pregnancy, either in the second-trimester patient who has "threatened miscarriage" or during sonographic assessment for fetal well-being and size. However, ultrasonography is only 58% sensitive, and diagnosis of partial mole is made in 17% of cases.[52] Up to two thirds of molar pregnancies are diagnosed by pathologic specimens after miscarriage.[52]

COMPLICATIONS OF LATE PREGNANCY

Vaginal Bleeding in Later Pregnancy

Perspective

Bleeding during the second half of pregnancy occurs in approximately 4% of pregnancies. Only 20% of miscarriages occur after the first trimester, and the most important differential diagnoses after 12 to 14 weeks of gestation are abruptio placentae and placenta previa. The cause is often not determined, although occult marginal placental separations (which can be recognized only by placental inspection at delivery) are held to be a common source of bleeding from above the cervix. Other causes of late vaginal bleeding include early labor, various cervical and vaginal lesions, lower genital tract infections, and hemorrhoids.

Bleeding during the second trimester before the fetus is potentially viable (14-24 weeks) is not benign. One third of fetuses are ultimately lost when maternal bleeding occurs. Management is supportive and expectant because fetal rescue is impossible at this level of fetal immaturity. In the third trimester, vaginal bleeding is still associated with significant morbidity in approximately one third of women, but the treatment includes consideration of urgent delivery.[53]

Abruptio Placentae

Principles of Disease. Abruptio placentae, or separation of the placenta from the uterine wall, is believed to account for approximately 30% of episodes of bleeding during the second half of pregnancy. In addition, small subclinical or marginal separations may go undetected until the placenta is examined at delivery and probably account for many of the other self-limited episodes of bleeding for which no diagnosis is made. In cases of nontraumatic abruptio placentae, apparently spontaneous hemorrhage into the

www.ketabpezeshki.com 66485457-66963820

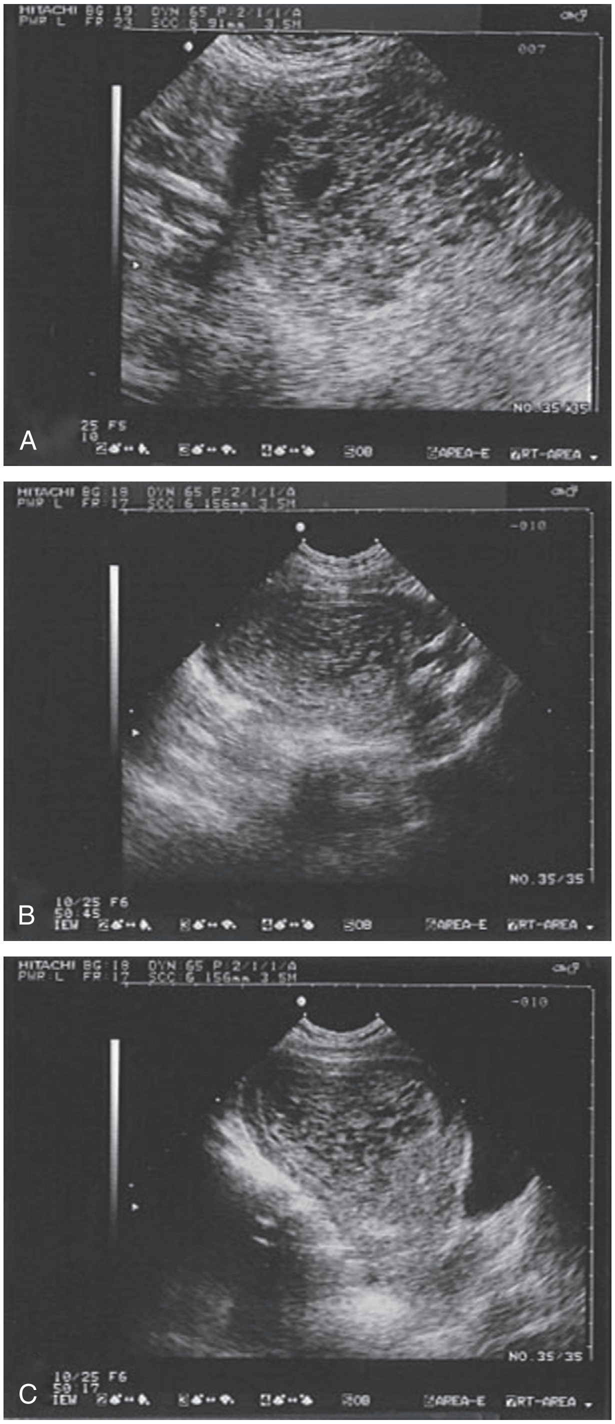

Figure 178-7. Ultrasonography showing molar pregnancy. (Courtesy Mary Ann Edens, MD.)

decidua basalis occurs, causing separation and compression of the adjacent placenta. Small amounts of bleeding may be asymptomatic and remain undetected until delivery. In other instances, the hematoma expands and extends the dissection; bleeding may be concealed or may be clinically apparent if dissection occurs along the uterine wall and through the cervix. Placental separation can be acute or an indolent problem throughout late pregnancy.

Abruptio placentae is most clearly associated with maternal hypertension and preeclampsia; it is also more common with increasing maternal age and parity, history of smoking, thrombophilia, prior miscarriage, prior abruptio placentae, and cocaine use.[53,54] Placental separation can also be associated with blunt trauma to the abdomen. In such instances, the cause appears to be shearing of a nonelastic placenta from the easily distorted elastic uterine wall at the time of traumatic impact. Women who reported physical violence during pregnancy were twice as likely as women who did not report violence to have an abruption.[55]

Clinical Features. Vaginal bleeding occurs in 70% of patients with abruptio placentae.[55] Blood is characteristically dark and the amount is often insignificant, although the mother may have hemodynamic evidence of significant blood loss. Uterine tenderness or pain is seen in approximately two thirds of women; uterine irritability or contractions are seen in one third. With significant placental separation, fetal distress occurs and the maternal coagulation cascade may be triggered, causing disseminated intravascular coagulation.[53]

There is a wide spectrum of severity of symptoms and risk in placental separation. Up to 20% of women will have no pain or vaginal bleeding.[54] Assessment is generally based on clinical features, coagulation parameters, and signs of fetal distress. Slight vaginal bleeding, little or no uterine irritability, absence of signs of fetal distress, and normal coagulation characterize mild abruption. As the separation becomes more extensive, it is associated with more vaginal bleeding (or hidden maternal blood loss), increased uterine irritability with or without tetanic contractions, declining fibrinogen levels, and evidence of fetal distress and maternal tachycardia. In cases of severe abruptio placentae (15% of cases), the uterus is tetanically contracted and very painful, maternal hypotension results from visible or concealed uterine blood loss, fibrinogen levels are less than 150 mg/dL, and fetal death can occur. Ultrasonography is insensitive in the diagnosis of abruptio placentae, often because the echogenicity of fresh blood is so similar to that of the placenta. Symptomatic or even fetus-threatening abruption can occur in the presence of a normal sonogram.[53]

Fetal distress and death occur in approximately 15% of patients with abruptio placentae by interruption of placental blood and oxygen flow. Risk of fetal death increases in proportion to both the percentage of placental surface involved and the rapidity of separation. Fetal distress may result from the loss of placental blood flow, associated maternal hemorrhage (into the uterine cavity or externally), increased uterine tone, or resultant disseminated intravascular coagulation. Maternal death can result, usually from coagulopathy or exsanguination. Fetomaternal transfusion occurs in a significant minority of patients. Placental separation also predisposes the mother to amniotic fluid embolism.

Differential Considerations. The main alternative diagnosis in the woman with late-pregnancy bleeding is placenta previa, which is usually associated with painless, bright red bleeding and must be excluded with ultrasonography. Lower genital tract or rectal lesions and bloody show (blood-tinged cervical mucous plug) are also considerations.

In the patient with abdominal pain but no vaginal bleeding, abruptio placentae with concealed hemorrhage must be distinguished from other causes of abdominal pain in later pregnancy: complications of preeclampsia, pyelonephritis, various liver diseases, gallbladder disease, appendicitis, and ovarian torsion. Uterine irritability caused by abruptio placentae can also be confused with early labor; in one series, almost one fourth of patients were misdiagnosed as having premature labor until fetal distress occurred. If the patient has acute catastrophic hypotension, amniotic fluid embolus (with or without abruptio placentae) and uterine rupture must be considered.[53]

Placenta Previa

Principles of Disease. Placenta previa, or implantation of the placenta over the cervical os, is the other major cause of bleeding episodes during the second half of pregnancy. The risk of placenta

www.ketabpezeshki.com 66485457-66963820

previa is increased with maternal age, multiparity, cesarean section, and preterm labor.[56] Bleeding occurs when marginal placental vessels implanted in the lower uterine segment are torn, either as the lower uterine wall elongates or with cervical dilation near the time of delivery. Early bleeding episodes tend to be self-limited unless separation of the placental margin is aggravated by iatrogenic cervical probing or onset of labor.

Clinical Features. Painless, fresh vaginal bleeding is the most common symptom of placenta previa. In approximately 20% of cases, some degree of uterine irritability is present, but this is usually minor. Vaginal examination usually reveals bright blood from the cervical os. Digital or instrumental probing of the cervix should never be done during the second half of pregnancy because it can precipitate severe hemorrhage in the patient with an asymptomatic or minimally symptomatic placenta previa. In the ED, speculum examination of the vagina and cervix should be performed only in those settings in which obstetric consultation is not readily available. It should be limited to an atraumatic partial speculum insertion to identify whether the bleeding is coming from the cervical os (and a presumed placenta previa), hemorrhoids, or a vaginal lesion that might not require urgent management.

Most cases of placenta previa identified during the midtrimester resolve by the time of delivery as the lower uterine segment elongates and the placenta no longer overlaps the cervical os. Central or total previa (which occurs in approximately 20% of cases) can, however, cause severe hemorrhage, with risk of exsanguination for the fetus and mother.

Diagnostic Strategies. Ultrasonography is the diagnostic procedure of choice for localization of the placenta and diagnosis of placenta previa. Accuracy is excellent; visualization of the placenta as well as of the internal cervical os is required. The bladder should be emptied before examination for suspected placenta previa to avoid overdiagnosis of placenta previa. Transvaginal ultrasonography is safe and even more accurate for visualization of the relationships between the placenta and the internal os.[57]

Management

Patients who experience vaginal bleeding during late pregnancy should have immediate obstetric consultation and arrangements for safe transfer to an appropriate obstetric facility. Initial management consists of maternal stabilization, with establishment of two large-bore intravenous lines and fluid resuscitation, as well as continuous fetal monitoring if it is available. A baseline hemoglobin level should be obtained, and blood should be sent for type and crossmatch; baseline coagulation studies including platelet count, prothrombin time, and partial thromboplastin time should be performed; and fibrinogen level and the presence of fibrin split products should be determined. The normal fibrinogen level in pregnancy is 400 to 450 mg/dL; values below 300 mg/dL indicate significant consumption of coagulation factors.

Blood loss requiring transfusion can occur in patients with placenta previa or abruptio placentae. Fresh frozen plasma or fresh whole blood may be needed because of the coagulopathy associated with significant abruptio placentae. Fetomaternal hemorrhage can occur with abruption. If the Rh-negative patient has not yet received her routine Rh immune globulin prophylaxis at 28 weeks, 300 µg of Rh immune globulin should be administered within 72 hours (unless the father is known to be Rh negative).[58] Transfer to the obstetric unit should be expedited if the patient is stable, or it should be done after initiation of resuscitation if she is unstable. If transfer to another hospital is required, a high-risk transfer team should be used if bleeding is significant or if the fetus is in distress. Although the bleeding source may not be identified or may be relatively benign, assessment is best accomplished by obstetricians who are accustomed to evaluation of late-pregnancy complications and who can perform emergent cesarean section if it is needed.

In the obstetrics unit, fetal monitoring is continued. Ultrasonography is used primarily to locate the placenta and to diagnose placenta previa; it may not be reliable in confirming the diagnosis of abruptio placentae. On occasion, subplacental hemorrhages of abruptio placentae can be seen and changes in size of the collection can be monitored. If evidence of placenta previa is absent or equivocal, vaginal examination is performed in the delivery suite, where emergency cesarean section can be performed if uncontrolled bleeding is encountered.

Patients who have significant abruptio placentae may require early delivery (either vaginal or surgical, depending on fetal status). If placenta previa is diagnosed or if abruptio placentae is considered mild, the patient is admitted for close monitoring. The goal is to support the patient, ideally until fetal maturity is demonstrated and a successful delivery can be accomplished.

Pregnancy-Induced Hypertension (Preeclampsia and Eclampsia)

Perspective

Hypertension is observed in approximately 6 to 8% of pregnancies and is generally divided into several categories.[59] *Gestational hypertension* occurs during pregnancy, resolves during the postpartum period, and is recognized by a new blood pressure reading of 140/90 mm Hg or higher. *Preeclampsia* is gestational hypertension with proteinuria (>300 mg/24 hr), and *eclampsia* is the occurrence of seizures in the patient with signs of preeclampsia. Progression of preeclampsia to eclampsia is unpredictable and can occur rapidly. *Pregnancy-aggravated hypertension* is chronic hypertension with superimposed preeclampsia or eclampsia. *Chronic or coincidental hypertension* is present before pregnancy or persists more than 6 weeks postpartum.[59]

Approximately 2 to 7% of pregnancies are complicated by pregnancy-induced hypertension. The incidence of actual eclampsia has progressively declined, but it is still one of the major causes of maternal mortality. The risk of pregnancy-induced hypertension is greatest in women younger than 20 years; primigravidas; those with twin or molar pregnancies; those with hypercholesterolemia, pregestational diabetes, or obesity; and those with a family history of pregnancy-induced hypertension.[60]

Principles of Disease

Gestational hypertension/preeclampsia is a vasospastic disease of unknown cause unique to pregnant women. Vasospasm, ischemia, and thrombosis associated with preeclamptic changes cause injury to maternal organs, placental infarction and abruption, and fetal death from hypoxia and prematurity. The cause of eclampsia is not known, but recent research has centered on vascular responsiveness to endogenous vasopressors in the preeclamptic woman. Vascular responsiveness is normally depressed during pregnancy, which is a high-output, low-resistance state. Gestational hypertension is characterized by an even greater elevation in cardiac output, followed by an abnormally high peripheral resistance as clinical manifestations of the disease develop. In patients with preeclampsia, the cardiac output eventually drops as peripheral resistance rises.[61] The cause of these changes is not known, but endothelial dysfunction is purported to release vasoactive mediators and to result in vasoconstriction.[62] Antiplatelet agents during pregnancy have been reported to reduce the risk of development of preeclampsia, supporting the premise of an imbalance between levels of thromboxane and prostacyclin in preeclampsia.[63]

The vasospastic effects of gestational hypertension/preeclampsia are protean. Intravascular volume is lower than in normal

www.ketabpezeshki.com 66485457-66963820

pregnancy, central venous pressures are normal, and capillary wedge pressures are variable. Liver effects are believed to be due to hepatocellular necrosis and edema resulting from vasospasm. Renal injury causes proteinuria and may result in decreased glomerular filtration. Microangiopathic hemolysis may result from vasospasm, causing thrombocytopenia. Central nervous system effects include microvascular thrombosis and hemorrhage as well as focal edema and hyperemia.[60]

Clinical Features

Signs and Symptoms. The patient with gestational hypertension has mild systolic or diastolic blood pressure elevation, no proteinuria, and no evidence of organ damage. Mental status assessment, testing of reflexes, abdominal examination, liver function studies, and coagulation studies should yield normal results. Preeclampsia is associated with kidney changes and, in severe cases, other end-organ symptoms. Edema is often difficult to assess because pregnancy is normally associated with excess extracellular fluid and dependent edema, and it is no longer used as a criterion for preeclampsia. Proteinuria (300 mg/24 hr) is variable at any given time and may not be detectable in a random urine specimen.[59]

In cases of severe preeclampsia, diastolic blood pressure can exceed 110 mm Hg, proteinuria is more severe, and there is evidence of vasospastic effects in various end organs. Central nervous system effects commonly include headache or visual disturbances. Thrombocytopenia may be present, liver function test findings may be elevated, and the liver is often tender. Renal dysfunction may be indicated by oliguria and elevated creatinine levels in addition to proteinuria.

Complications. The HELLP syndrome, a particularly severe form of preeclampsia that develops in 5 to 10% of women who have preeclamptic symptoms, is characterized by *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count (100,000/mL). Prothrombin time, partial thromboplastin time, and fibrinogen level are normal, and blood studies reveal microangiopathic hemolytic anemia. Other complications of preeclampsia include spontaneous hepatic and splenic hemorrhage and abruptio placentae.

The most dangerous complication is eclampsia, which is the occurrence of seizures or coma in the setting of signs and symptoms of preeclampsia. Warning signs for development of frank eclampsia include headache, nausea and vomiting, and visual disturbances.[64] Elevated total leukocyte count, creatinine, and aspartate aminotransferase are also predictive of increased morbidity for the patient with severe preeclampsia.[65] Particularly in early eclampsia before 32 weeks of gestation, seizures may develop abruptly and hypertension may not be associated with edema or proteinuria.[66] In postpartum women who have eclampsia, more than half (55%) are not previously diagnosed with preeclampsia, and patients may present with headache, vision changes, elevated blood pressure, or seizure up to 4 weeks after delivery.[67] After 48 hours postpartum and without predelivery signs of preeclampsia, other diagnoses, such as intracranial hemorrhage, should be considered. Maternal complications of eclampsia include permanent central nervous system damage from recurrent seizures or intracranial bleeding, renal insufficiency, and death.

The maternal mortality rate from eclampsia has been reduced with modern management and is currently less than 1%. Perinatal mortality has also decreased, although it remains 4 to 8%.[60] Causes of neonatal death include placental infarcts, intrauterine growth retardation, and abruptio placentae. In addition, fetal hypoxia from maternal seizures and the complications of premature delivery contribute significantly to fetal mortality and morbidity.

Diagnostic Strategies

The patient who has severe preeclampsia should have an intravenous line and fetal monitoring initiated in a quiet but closely observed area. Blood testing should include complete blood cell count, renal function studies, liver function tests, platelet count, and coagulation profile. A baseline magnesium level should also be obtained. In the patient with actual seizures, serum glucose concentration should be tested. If a history of preeclampsia is not obtained or the symptoms are refractory to magnesium sulfate therapy, a computed tomography (CT) scan of the head should be performed to exclude cerebral venous thrombosis or an intracranial bleed, either of which can occur in pregnancy (with or without pregnancy-induced hypertension) and may require specific treatment. CT scan abnormalities can be seen in half of patients with eclampsia. Patchy hemorrhage and microinfarcts of the cortex are characteristic and may be due to loss of cerebral autoregulation in patients with severe pregnancy-related hypertension. Diffuse cerebral edema can also be seen.[68]

Differential Considerations

Peripheral edema is common in normal pregnancy, and it may be difficult to differentiate normal edema from that of early preeclampsia. Differentiation of gestational hypertension from preexistent hypertension is often impossible if no record of normal blood pressure is available. Seizures during pregnancy may be due to epilepsy as well as other intracranial catastrophes, such as thrombosis or hemorrhage.

Management

In the patient who has mild preeclampsia, appropriate management includes documentation of blood pressure and reflexes, weight, and testing to ensure normal end-organ function. Accurate determination of gestational age by ultrasonography is needed to allow optimal management if symptoms progress. Limitation of physical activities (including bed rest) is the only demonstrated means of reducing blood pressure and allowing the pregnancy to be sustained longer. Definitive treatment is delivery of the fetus, although expectant management is standard in women at less than 34 weeks of gestation. Arrangement for close follow-up is important for patients who are not hospitalized.

Hospitalization is usually required for patients with sustained hypertension above 140/90 mm Hg and signs of severe preeclampsia. Baseline laboratory studies to identify end-organ effects in the liver, kidney, and hematologic systems should be obtained. Both diuresis and antihypertensive therapy have been remarkably unsuccessful in improving fetal outcome or prolonging pregnancy. Admission does, however, allow the obstetrician to accurately assess fetal age and well-being, maternal organ function, and the effect of bed rest on blood pressure before the optimal timing of delivery is decided.[59]

Fulminant or severe preeclampsia, with marked blood pressure elevation (160/110 mm Hg) associated with epigastric or liver tenderness, visual disturbance, or severe headache, is managed in the same way as eclampsia (Box 178-4). The goal is prevention of seizures and permanent damage to maternal organs. Magnesium sulfate is given for seizure prophylaxis.

Seizures and coma are the hallmarks of eclampsia, the ultimate consequence of preeclampsia. As in all seizure patients, hypoglycemia, drug overdose, and other causes of seizures should be excluded with appropriate tests. Eclamptic seizures are controlled in almost all patients by adequate doses of magnesium sulfate, although the mechanism of action remains elusive. Magnesium has little antihypertensive effect but is the most effective anticonvulsant, preventing recurrent seizures while maintaining uterine

www.ketabpezeshki.com 66485457-66963820

Box 178-4 Management of Eclampsia and Severe Preeclampsia

Control seizures with magnesium sulfate.
Control hypertension after seizure control if diastolic blood pressure >105 mm Hg.
Obtain initial laboratory studies to assess organ injury:
- Complete blood count and platelet count
- Liver function tests
- Blood urea nitrogen, creatinine

Monitor urine output: maintain at <25 mL/hr.
Limit intravenous fluid administration unless significant losses occur.
Avoid diuretics and hyperosmotic agents.
Perform a computed tomography scan of head if consciousness is decreased or seizures persist, lateralizing signs are present, or there are other concerns.
Initiate steps to delivery.

Modified from Pritchard J, et al: The Parkland Memorial Hospital protocol for treatment of eclampsia: Evaluation of 245 cases. Am J Obstet Gynecol 161:261, 1989.

and fetal blood flow. The goals of magnesium sulfate therapy are to terminate ongoing seizures and to prevent further seizures. An intravenous loading dose of 6 g magnesium, followed by 2 g/hr intravenously, is recommended. Magnesium administration should be accompanied by clinical observation for loss of reflexes (which occurs at approximately 10 mg/dL) or respiratory depression (which occurs at levels of 12 mg/dL, although actual serum magnesium levels are rarely monitored). The infusion should be stopped if signs of hypermagnesemia are seen; such patients may require assisted ventilation. Calcium gluconate, 1 g given slowly into a secure vein, will reverse the adverse effects of hypermagnesemia.[60]

Despite ongoing controversy, the familiarity with magnesium sulfate and its physiologic advantages to the fetus, wide margin of safety, and high success rate in controlling seizures make it the first-line drug in patients with eclampsia. A Cochrane review found that magnesium sulfate is more effective than other anticonvulsants and diazepam for prophylaxis against or treatment of eclamptic seizures, more than halving the risk.[69] If seizures persist after the recommended doses of magnesium sulfate have been administered, further therapy should be given in conjunction with obstetric consultation, and a careful search for other causes of seizures (e.g., hypoglycemia and intracranial bleed) should be instituted.

Although magnesium sulfate is not a direct antihypertensive, the hypertension associated with eclampsia is often controlled adequately by stopping of the seizures. Rapid lowering of blood pressure can result in uterine hypoperfusion, so specific antihypertensive treatment is initiated only if the diastolic blood pressure remains above 105 mm Hg after control of seizures. Many patients do not require specific antihypertensive treatment after treatment with magnesium sulfate. The antihypertensive used most often by obstetricians is hydralazine. The dose is 5 mg intravenously, with repeated doses of 5 to 10 mg intravenously every 20 minutes as needed to keep the diastolic blood pressure below 105 mm Hg. Nimodipine and labetalol have also been reported to be safe and effective, although they are less widely used.[70] Other antihypertensive agents are not well studied in this population because there are specific risks to uncontrolled lowering of blood pressure and loss of uteroplacental blood flow.

Although total body water in the eclamptic patient is excessive, intravascular volume is contracted and the eclamptic patient is sensitive to further volume changes. Hypovolemia results in decreased uterine perfusion. Thus diuretics and hyperosmotic agents should be avoided in patients with eclampsia. Although intravascular volume expansion in the face of volume contraction, increased systemic resistance, and vasospasm would seem reasonable, invasive monitoring has demonstrated that vasospasm is not reversed with intravenous fluid administration. Rather, excessive intravenous fluids increase extravascular fluid stores that are difficult to mobilize postpartum, resulting in a higher incidence of pulmonary edema in patients treated aggressively with fluid therapy. Invasive pulmonary artery pressure monitoring may be required for accurate fluid management in the eclamptic patient.

Amniotic Fluid Embolus

Perspective

Amniotic fluid embolus is the release of amniotic fluid into the maternal circulation during intense uterine contractions or uterine manipulation or at areas of placental separation from the uterine decidua basalis (abruptio placentae), triggering a rapidly fatal anaphylactoid-type maternal response. Although amniotic fluid embolus most commonly occurs during labor, in which circumstance the maternal mortality rate is 25% or higher, it can also occur after induced abortions and miscarriages and spontaneously during the second and third trimesters. Amniotic fluid embolus can also occur after amniocentesis or in association with abruptio placentae after abdominal trauma. Although it is a rare syndrome, amniotic fluid embolus is responsible for 13 to 30% of maternal deaths and is the second leading cause of direct maternal death.[71]

Clinical Features

Amniotic fluid embolus should be suspected during the second or third trimester of pregnancy, particularly in the setting of uterine manipulation or contraction, when a patient experiences sudden hypotension, hypoxia, and coagulopathy. The embolization of amniotic fluid and the particulate matter suspended in it triggers a profound immunologic response when it enters the maternal circulation. The list of proposed mediators is extensive and includes histamine, endothelin, and leukotrienes.[71] In survivors, disseminated intravascular coagulation, acute respiratory distress syndrome, and left ventricular dysfunction develop. An initial seizure is seen in approximately 20% of patients. Bleeding diathesis may be the initial sign in some women, and disseminated intravascular coagulation occurs in approximately 50%.

Diagnostic Strategies

When amniotic fluid embolus is suggested, a complete blood cell count, coagulation studies, arterial blood gas analysis, and chest radiograph should be obtained. Urine output should be monitored after urinary catheter placement. The diagnosis is usually made with certainty only at autopsy, with the finding of fetal hairs, squamous cells, and debris in the maternal circulation. Because squamous epithelial cells can be seen normally in the maternal pulmonary circulation, the typical clinical syndrome is also required for diagnosis.[71]

Differential Considerations

Catastrophic pulmonary embolus, drug-induced anaphylaxis, and septic shock must be considered in the differential diagnosis. Seizure occurs in patients with eclampsia, but hypertension rather than cardiovascular collapse should be observed in that condition. Coagulopathy may be seen in patients with preeclampsia (HELLP

www.ketabpezeshki.com 66485457-66963820

syndrome), abruptio placentae, or other chronic coagulopathies seen in the nonpregnant patient.

Management

Amniotic fluid embolus is uncommon, so treatment is mainly anecdotal and based on animal studies. The most helpful modalities appear to be high-flow oxygen, support of ventilation and oxygenation with intubation, aggressive fluid resuscitation, inotropic cardiovascular support, and anticipation and management of consumptive coagulopathy. Adequate management usually requires invasive hemodynamic monitoring in an intensive care unit.

Rh (Anti-D) Immunization in Pregnancy

Rh immunization occurs when an Rh-negative woman is exposed to Rh-positive fetal blood. Small numbers of fetal cells enter the maternal circulation spontaneously throughout pregnancy, but the maternal immune system is triggered only by significant loads of fetal cells, which can occur during the third trimester and at delivery. Sensitization occurs in up to 15% of Rh-negative women carrying Rh-positive fetuses. To prevent this, anti-D immune globulin (RhoGAM) is routinely administered to Rh-negative mothers (if the father is Rh positive or his status is unknown) at approximately the 28th week of gestation to protect the mother from spontaneous sensitization, which occurs during the third trimester. Transplacental hemorrhage can also occur during uterine manipulation, threatened miscarriage (even without fetal loss), spontaneous miscarriage, surgery for ectopic pregnancy, and amniocentesis, although the risk is not clear. Anti-D immune globulin should be administered when these events occur. A dose of 50 μg can be used if the patient is at less than 12 weeks of gestation, although many pharmacies carry only the 300-μg dose, which can also be given. After 12 weeks, a 300-μg dose should be given. The half-life of immune globulin is 24 days, and it needs to be administered within 72 hours of a sensitization event to prevent antibody development.[14]

The Kleihauer-Betke test of maternal blood has been used to detect fetal cells in the maternal circulation. Unfortunately, the test is difficult to perform, not immediately available in most emergency laboratories, and only sensitive enough to detect 5 mL of fetal cells in the maternal circulation. Because only 0.1 mL of fetal cells is required to sensitize the mother, routine immune globulin administration has been recommended in situations likely to result in sensitization. Patients with third-trimester bleeding are not at increased risk of sensitization compared with patients with normal pregnancy; RhoGAM should be administered only if the patient did not receive her prophylactic dose at 28 weeks.[58] In instances of significant blunt trauma to the uterus, the Kleihauer-Betke test should be ordered to detect the rare large fetal transfusions that may require specific fetal blood therapy or administration of additional immune globulin to the mother. The standard dose (300 μg) is sufficient to prevent maternal immunization for fetal transfusions of up to 15 mL of red blood cells or 30 mL of whole blood.[14]

MEDICAL AND SURGICAL PROBLEMS IN THE PREGNANT PATIENT

Perspective

Clinicians should be aware of a variety of illnesses, both related and unrelated to pregnancy, that may have altered symptoms, risk, and treatment in the pregnant patient (Tables 178-2 and 178-3).

Table 178-2 Differential Diagnosis of Abdominal Pain in Pregnancy

DIAGNOSIS	GESTATIONAL AGE	COMMENTS
Gynecologic		
Miscarriage	<20 weeks, 80% <12 weeks	Ultrasonography to confirm location
Septic abortion	<20 weeks	Fever, uterine tenderness
Ectopic pregnancy	<14 weeks	Must always be considered in first trimester until intrauterine pregnancy confirmed
Corpus luteum cyst	<12 weeks	Sudden focal peritoneal pain; no fever
Ovarian torsion	Especially <24 weeks	Ischemic pain
Pelvic inflammatory disease	<12 weeks	Very rare
Chorioamnionitis	>16 weeks	Tender uterus, fever; amniocentesis reveals white blood cells
Abruptio placentae	>16 weeks	Focal uterine tenderness, fetal distress, variable bleeding
Preeclampsia	>20 weeks	Hypertension, proteinuria, edema, right upper quadrant pain
Nongynecologic		
Appendicitis	Throughout	Guarding may be less prominent; location changes
Cholecystitis	Throughout	Confirm with ultrasonography
Hepatitis	Throughout	Confirm with liver function tests
Pyelonephritis	Throughout	Flank pain, fever, positive catheterized urinalysis

Abdominal Pain

Appendicitis

Perspective. Appendicitis is the most common surgical emergency in pregnant patients. The incidence of appendicitis in pregnant patients is the same as that in nonpregnant patients, but delays in diagnosis contribute to an increased rate of perforation, which results in significant fetal mortality and maternal morbidity.[72,73] During the first half of pregnancy, diagnostic findings are usually similar to those in the nonpregnant woman, but the clinical picture becomes less classic during the second half of pregnancy.

Principles of Disease. Traditionally, the appendix was thought to be displaced counterclockwise out of the right lower quadrant after the third month of gestation, with its ultimate location deep in the right upper quadrant, superior to the iliac crest (Fig. 178-8). However, one study found that in only 23% of pregnant patients does the location change from the right lower quadrant, even in the third trimester.[74] Displacement of the abdominal wall away from the abdominal viscera can result in difficulty in palpation of organs and loss of signs of parietal peritoneal irritation. The physiologic increase in white blood cell count and erythrocyte sedimentation rate in pregnancy should also be considered in the evaluation of the patient with possible appendicitis because these may confuse the overall clinical picture.

www.ketabpezeshki.com 66485457-66963820

Table 178-3 Differential Diagnosis of Common Symptoms in Pregnancy

DIAGNOSIS	GESTATIONAL AGE	COMMENTS
Vaginal Bleeding		
Miscarriage	<20 weeks	Usually no fetal heart activity at 8 weeks; decreasing hCG level
Ectopic pregnancy	<14 weeks	Evaluate with ultrasonography
Molar pregnancy	12-24 weeks	No fetal heart tones, characteristic sonogram
Cervical lesions	Throughout	Perineal and vaginal inspection
Vaginitis, cervicitis	Throughout	White blood cells on wet mount, with culture
Placenta previa	>16 weeks	Ultrasonography to localize placenta
Abruptio placentae	>16 weeks	Ultrasonography to exclude previa; fetal distress, tenderness
Seizure		
Eclampsia	>24 weeks	Blood pressure >140/90 mm Hg; usually history of PIH, edema, proteinuria
Amniotic fluid embolus	>12 weeks	Hypotension, respiratory distress, DIC
Epilepsy	Throughout	History; lack of PIH findings
Dyspnea		
Pulmonary embolus	Especially 6 weeks prepartum and postpartum	Usual diagnostic studies
Dyspnea of pregnancy	>24 weeks	Exclude other causes
Pulmonary infection	Throughout	Examination; radiography
Amniotic fluid embolus	>12 weeks	Uterine manipulation, bleeding diathesis, hypotension
Jaundice		
Cholestasis of pregnancy	>24 weeks	Well patient; itching and jaundice
Hepatitis	Throughout	Abnormal liver function test results
Acute fatty liver	>24 weeks	Rapid liver failure; coma, seizures, hypoglycemia
Bleeding Diathesis		
Eclampsia	>24 weeks	Blood pressure >140/90 mm Hg; proteinuria, edema, HELLP syndrome
Amniotic fluid embolus	>12 weeks	Respiratory distress, cardiovascular collapse
Abruptio placentae	>20 weeks	Uterine tenderness; vaginal bleeding; fetal distress

DIC, disseminated intravascular coagulation; *hCG,* human chorionic gonadotropin; *HELLP,* hemolysis, elevated liver enzymes, low platelets; *PIH,* pregnancy-induced hypertension.

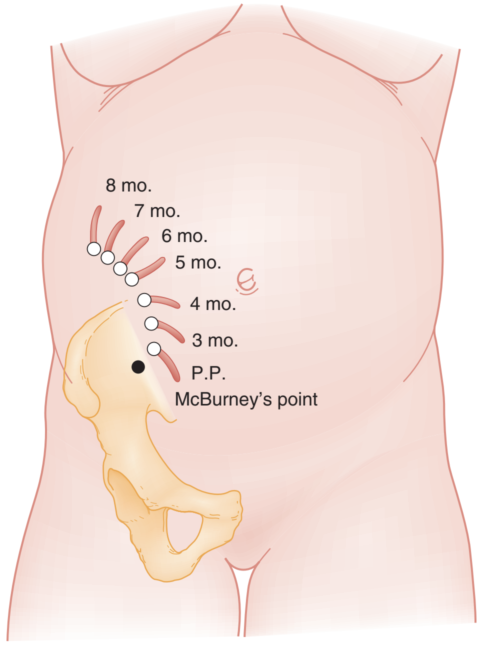

Figure 178-8. Locations of the appendix during succeeding months of pregnancy. In planning an operation, it is better to make the abdominal incision over the point of maximal tenderness unless there is great disparity between that point and the theoretic location of the appendix. *P.P.,* postpartum. (From Gabbe SG, et al [eds]: Obstetrics: Normal and Problem Pregnancies. New York, Churchill Livingstone, 2007. Redrawn from Baer JL, Reis RA, Arens RA: Appendicitis in pregnancy. JAMA 98:1359, 1932.)

Clinical Features. The gastrointestinal symptoms of appendicitis, such as anorexia, nausea, and vomiting, mimic those of pregnancy, particularly during the first trimester, making such symptoms relatively nonspecific. Right-sided abdominal pain is the most constant finding, although this is less reliable later in pregnancy. Peritoneal signs are likewise most common during the first trimester. Lack of fever, leukocytosis, or tachycardia has been reported.[74,75] The cause of these differences in clinical findings in pregnant patients with appendicitis may be a blunted inflammatory response from elevated maternal levels of pregnancy-related steroids. Pyuria without bacteriuria is seen in up to 58% of patients.[76]

Because of confounding factors, the misdiagnosis rate for appendicitis is 30 to 35% overall in pregnancy, with a 40 to 50% rate of removal of normal appendix during the third trimester.[74,76] In contrast to the relative safety of performing an exploratory laparotomy or laparoscopy during pregnancy, the risk of fetal loss and maternal morbidity from failure to diagnose appendicitis and perforation is considerable, so clinical vigilance is required even in the absence of classic signs. In later pregnancy, when peritoneal signs are often absent and the uterus obscures normal physical findings, diagnosis is frequently delayed, and the perforation rate may approach 25%.

Differential Considerations. Pyelonephritis, cholecystitis, nephrolithiasis, and pregnancy-related diseases such as ectopic pregnancy, broad ligament pain, corpus luteum cyst leakage, and ovarian torsion should be considered in the patient who has right-sided abdominal pain. Pyelonephritis is the most common condition that is confused with appendicitis. During its migration, the appendix takes up a position very near the kidney, resulting in a high incidence of pyuria and flank pain (see Fig. 178-8). In cases of appendicitis, unless there is coincident urinary tract infection, the urine is free of bacteria, a feature distinguishing it from

www.ketabpezeshki.com 66485457-66963820

pyelonephritis. Salpingitis, another common misdiagnosis, is very rare in pregnancy, although it can occur before 12 weeks of gestation.

Diagnostic Strategies. Leukocytosis is common in pregnant patients with appendicitis, although it is rarely high enough to distinguish it from the physiologic leukocytosis of pregnancy. Pyuria in a catheterized urine specimen suggests pyelonephritis, but it is also seen in 20% of patients with appendicitis.[74] Bacteriuria is uncommon. Ultrasonography, with graded-compression techniques, may reveal a noncompressible tubular structure in the right lower quadrant consistent with appendicitis. Studies regarding the diagnostic utility of ultrasonography in the diagnosis of appendicitis are limited but suggest that it has a high positive predictive value but a low negative predictive value.[76,77] Butala and colleagues recommend abdominal ultrasonography as the first imaging modality for patients, and if it is inconclusive, CT is the next imaging modality.[78] When it is available, magnetic resonance imaging (MRI) is also useful in evaluation of pregnant patients with suspected appendicitis (see Chapter 93). Otherwise, laparoscopy or laparotomy is the diagnostic procedure of choice in the pregnant patient thought to have appendicitis. Early exploration is to be encouraged even more in pregnant than in nonpregnant patients because of the variability of clinical signs and the increased fetal risk if diagnosis is delayed.

Management. The pregnant patient with suspected appendicitis should be admitted to the hospital after appropriate consultation with surgeons and obstetricians. Ultrasonography, MRI, or CT scan should be considered diagnostic options. The patient should be kept on nothing by mouth (NPO) status, with intravenous fluid hydration to maintain intravascular volume. Although prompt surgery is required if the diagnosis is clear, in unclear cases a period of inpatient observation may allow clarification of signs and symptoms.

Gallbladder Disease

Perspective. Cholelithiasis is present in approximately 5% of pregnant women and is the second most common nonobstetric surgical condition in pregnant patients. The natural history of asymptomatic cholelithiasis is believed to be similar to that in nonpregnant women, with less than half of patients with gallstones developing symptoms.[79]

Principles of Disease. Changes in gallbladder kinetics are believed to be due to high pregnancy-related steroid levels. Progesterone decreases smooth muscle tone and induces gallbladder hypomotility and cholestasis, causing an increased risk of stone formation. In addition, pregnancy induces changes in bile composition and increased cholesterol secretion, thus increasing the incidence of cholesterol stone formation.[80]

Clinical Features. The signs and symptoms of acute cholecystitis during pregnancy are the same as those in nonpregnant women. Epigastric or right upper quadrant pain and tenderness and nausea predominate. Leukocytosis must be interpreted carefully because of the increased white blood cell count seen normally in pregnancy. Likewise, a slightly elevated amylase level can be normal during pregnancy, and alkaline phosphatase, which is produced by the placenta, may be twice the nonpregnant level. A history of self-limited pain episodes associated with food intake is useful in suggesting the diagnosis.

Diagnostic Strategies. Ultrasonography is a reliable means of recognizing stones within the gallbladder, although it may not differentiate symptomatic from asymptomatic stones. In the patient with right upper quadrant pain, simultaneous sonographic evaluation of the liver is useful but technically difficult, particularly during the third trimester, when subcapsular liver hematomas and other intrinsic hepatocellular disease can occur but the liver may be obscured under the ribs.

Differential Considerations. Pyelonephritis should be considered in the patient with right upper quadrant pain with or without fever. During the third trimester, appendicitis can also be associated with right upper quadrant pain. Hepatitis and fatty liver infiltration occur in pregnancy; liver distention and inflammation associated with pregnancy-induced hypertension can also cause right upper quadrant pain. In addition, spontaneous intrahepatic bleeding can occur in late pregnancy, mimicking cholecystitis. Because of the potential for other serious diseases, diagnostic studies should always be performed to verify a clinical diagnosis of symptomatic cholelithiasis and cholecystitis in pregnancy.

Management. The patient who has fever, leukocytosis, prolonged pain, or evidence of cholecystitis should be made NPO and given intravenous fluid hydration, adequate pain control, and broad-spectrum antibiotics. These patients must be admitted for inpatient management. Some patients can be managed medically for prolonged or complicated cholecystitis. Patients with obstructive jaundice, gallstone pancreatitis, or sepsis or patients who fail to respond to conservative management should have surgery. Discharge should be considered only in patients with uncomplicated and sonographically proven cholelithiasis who do not meet admission criteria after consultation with an obstetrician. Pregnant patients with symptomatic cholelithiasis have a high rate of symptomatic relapse and increased severity of disease with each relapse.[81] Early follow-up should be arranged and the patient should be given careful instructions to return if she experiences fever, vomiting, or persistent pain. In one study, patients who were observed during pregnancy had a higher rate of pregnancy-related complications (36%) in contrast to much lower rates of complications in those who had laparoscopic cholecystectomy.[82]

Liver Disorders

Perspective. Pregnancy is associated with several unique liver abnormalities in addition to more usual hepatic diseases. Clinicians should recognize the various symptoms of liver disease during pregnancy as well as the hepatic diseases unique to pregnant women. Liver metabolism increases during pregnancy, but hepatic blood flow is unchanged, and little change occurs in liver function. Bilirubin, transaminase, and lactate dehydrogenase levels and prothrombin times are unchanged from the nonpregnant state. Albumin levels decrease secondary to an increase in maternal circulating plasma volume. Alkaline phosphatase levels may be up to double the nonpregnant values, and amylase levels may also be slightly elevated.[83,84]

Hepatitis

Hepatitis is the most common cause of liver disease in pregnancy, accounting for 40% of cases of jaundice in pregnancy. Management and treatment are supportive and unchanged from those for nonpregnant patients. Hepatitis E, however, has been reported to have a more aggressive course in pregnancy.[84] Maintenance of adequate nutrition is a priority. Vertical transmission of hepatitis B can occur if the disease is not recognized. Prophylaxis should be administered to the newborn.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy is a disorder of the third trimester that can result in hepatic failure, complicated labor, and fetal mortality. The disease is rare, occurring most often in primiparous patients and patients with twin gestations.

Principles of Disease. The cause of acute fatty liver of pregnancy is unknown, although studies suggest that a deficiency in the fetus's fatty acid metabolism leads to an accumulation of hepatotoxic metabolites in the maternal circulation.[84-87] On microscopic examination, fatty infiltration of the hepatocytes with edema and vacuolization can be seen, but there is no necrosis or

www.ketabpezeshki.com 66485457-66963820

inflammation. Liver function returns to normal after delivery if the patient can be supported through the acute phase. Although up to 50% of patients have signs of preeclampsia, the two are not clearly related.[87] The diagnosis must be differentiated from viral hepatitis and HELLP syndrome, which have similar disease presentations and laboratory findings but, again, are not clearly related.[84,85]

Clinical Features. Nausea and vomiting associated with malaise or jaundice during the third trimester should trigger consideration of a diagnosis of acute fatty liver.[88] The right upper quadrant or epigastrium is usually tender. The disease may progress to coagulopathy, jaundice, seizures, disseminated intravascular coagulation, and hepatic encephalopathy. The diagnosis is often delayed secondary to the multiple differential considerations.

Diagnostic Strategies. Typically, leukocytosis is present, the platelet count and fibrinogen level are low, prothrombin time and partial thromboplastin time are elevated, and fibrin split products are present. In a series of 11 patients, raised transaminase and serum bilirubin concentrations were found in all patients, hypoglycemia was found in 18%, and hypoproteinemia was found in 46%.[88] In contrast to Reye's syndrome, the serum ammonia level is only mildly elevated. Hyperuricemia is usually present. Bilirubin is elevated late in the course of the disease. The CT scan and the sonogram may be normal, so liver biopsy is used to make the definitive diagnosis.

Differential Considerations. Liver tenderness and coagulopathy most often suggest preeclampsia during the third trimester. Jaundice and increases in aminotransferase level are distinguishing features because they are unusual in cases of liver disease associated with pregnancy-induced hypertension. Similarly, rapid progression of hepatic failure, hypoglycemia, and coagulopathy is unlikely in cases of preeclampsia. The patient with viral hepatitis is likely to have more marked elevations in transaminase levels. Drug-induced hepatic failure should be excluded by history and toxicologic screen for acetaminophen or other toxins if appropriate. Cholecystitis may be distinguished by ultrasound examination, but it may also be characterized by right upper quadrant pain; it is not associated with coagulopathy or progressive liver failure.

Management. The patient with acute fatty liver of pregnancy requires immediate stabilization if she is experiencing seizure or coma. Hypoglycemia may occur, which should be rapidly corrected with dextrose. Coagulation parameters should be assessed. Fluid resuscitation and replacement of clotting factors may be required, and the patient should be admitted to an obstetric service capable of managing this serious disease. The diagnosis is usually made with liver biopsy if the disease has not progressed to severe coagulopathy. Rapid delivery is usually advisable when the diagnosis has been established. Fresh frozen plasma, platelet transfusions, and glucose may be needed to sustain the patient until delivery can be accomplished.

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy, also termed idiopathic jaundice of pregnancy, icterus gravidarum, or pruritus gravidarum, is a rare syndrome that occurs during the third trimester of pregnancy. It is the second most common cause of jaundice in pregnancy, after hepatitis. On histologic examination, the disease is characterized by cholestasis and dilated canaliculi in the biliary tree. The liver is normal. It is more common with increasing maternal age, with multiple gestations, and in the winter months.[84]

Clinical Features. Generalized pruritus and mild jaundice are the hallmarks of intrahepatic cholestasis of pregnancy. Only 20% of patients present with this combination, however, and 80% present with pruritus alone. The pruritus usually begins in the palms and soles and ascends to the trunk. Although insomnia and fatigue occasionally accompany the pruritus, the patient appears nontoxic, without fever, vomiting, diarrhea, or significant malaise. The bilirubin level is rarely above 5 mg/dL, the alkaline phosphatase level can be elevated sevenfold to tenfold, and transaminase levels are in the normal range. Resolution occurs when the woman delivers. Although maternal outcome is favorable, women with intrahepatic cholestasis of pregnancy are at increased risk for preterm delivery, meconium passage, and intrauterine fetal demise.[84,89]

Differential Considerations and Management. Exclusion of more serious entities, such as viral hepatitis, acute fatty liver, drug-induced cholestasis, and complicated cholecystitis, is required. Outpatient management is appropriate, provided the diagnosis is clear and the patient has close obstetric follow-up. Some authors advocate aggressive fetal surveillance and delivery after fetal lung maturity to improve fetal outcome.[84] Symptomatic treatment with antihistamines, ursodeoxycholic acid, bile salts, guar gum, benzodiazepines, and other medications has been tried with variable success.[90]

Hyperemesis Gravidarum

Nausea and vomiting are common in pregnancy, particularly from 6 to 20 weeks of gestation. Hyperemesis gravidarum is defined as nausea and vomiting that cause starvation metabolism, weight loss, dehydration, and prolonged ketonemia and ketonuria. It occurs in a small minority of pregnant patients. The cause of hyperemesis gravidarum is not clear; associations have been made with increasing estradiol and hCG levels as well as with maternal cytokines.[91,92] Several studies have suggested an increased infection rate with *Helicobacter pylori* in patients with hyperemesis gravidarum, and Mansour showed that a nonteratogenic regimen for *H. pylori* treatment resulted in decreased vomiting in hyperemesis patients.[93] Initial management involves rehydration with intravenous fluids, antiemetics, and demonstration of ability to take oral hydration. Patients may require enteral nutrition. Most standard antiemetics are in Food and Drug Administration category C and are used successfully to treat hyperemesis gravidarum.[94] A short course of oral prednisolone has been reported to be therapeutic for intractable hyperemesis.[95,96] Oral vitamin B_6 has also been reported to be helpful.[97] Bilirubin and alkaline phosphatase levels can be mildly elevated but should return to normal after delivery. Hyperemesis may be complicated by liver disease and abnormal liver function test results, which are expected to resolve with supportive treatment.[97]

Thromboembolic Disease in Pregnancy

Principles of Disease

Thromboembolic disease accounts for almost 20% of obstetric mortality, making it the leading cause of death in pregnancy.[24] Pregnancy is a hypercoagulable state, with increased coagulation factors and stasis as pregnancy progresses and significant vascular trauma at the time of delivery. The risk of venous thrombosis increases during pregnancy to five or six times that of nonpregnant women. Although the risk is increased throughout pregnancy, it is highest during the puerperium. Risk factors include smoking, obesity, age older than 35 years, hypercoagulable state, varicose veins, and prior superficial venous thrombosis. Women who deliver prematurely or have postpartum hemorrhage are also at higher risk.[98-101]

Clinical Features

As in nonpregnant patients, clinical signs of pain, tenderness, and swelling are poor predictors of deep venous thrombosis (DVT) in pregnancy. The clinical diagnosis of pulmonary embolus (PE) is

www.ketabpezeshki.com 66485457-66963820

likewise difficult. Although tachypnea, tachycardia, dyspnea, and pleuritic pain are commonly associated with PE, the symptoms are nonspecific and may be associated with such diverse diseases as hepatic inflammation, pyelonephritis, and diaphragmatic impingement from a normal gravid uterus.

Diagnostic Strategies

Arterial blood gas analysis may not be very helpful in the diagnosis of PE. The alveolar-arterial oxygen gradient is a poor screening test for PE in pregnancy and postpartum, with a sensitivity of 77% and specificity of 20%.[102] A chest radiograph (shielding the pelvis and uterus) should be obtained to exclude other disease processes that may mimic a PE. The diaphragm is normally symmetrically elevated during late pregnancy.

Because of its widespread availability, Doppler ultrasonography has superseded noninvasive impedance plethysmography as the first-line test for the diagnosis of DVT. Both tests, however, are useful in the diagnosis of DVT of the femoral or popliteal veins in pregnancy, and these studies provide the least risk to the patient. An abnormal flow study finding is sufficient reason to treat the pregnant patient in most cases. However, normal leg study results can be seen with isolated iliac vein disease, which is common in pregnancy and requires imaging with MRI or CT for diagnosis. If thromboembolic disease is suspected, serial indirect Doppler testing or CT may be required.[103] The risk of anticoagulation usually outweighs the risk of definitive studies when the diagnosis is equivocal.

Currently, studies do not support D-dimer tests in pregnancy to exclude the diagnosis of PE as this test may lack sufficient sensitivity in pregnant patients.[104] Thus imaging is recommended, usually lung scintigraphy or CT. Lung scintigraphy and CT angiography have comparable performances for PE diagnosis during pregnancy, although CT angiography delivers higher maternal radiation dose.[105] Pulmonary angiography may be required if the diagnosis of PE is unclear after less invasive studies have been performed.

Management

Warfarin (Coumadin) is contraindicated during pregnancy because of its teratogenic effects and high risk of abortions and fetal hemorrhage. Heparinoids are used to treat thromboembolic disease during pregnancy. Unfractionated heparin carries a poorly understood risk of fetal osteoporosis, thrombocytopenia, prematurity, or miscarriage. In general, acute anticoagulation with intravenous heparin is followed by subcutaneous heparin twice daily, usually continued for 3 to 6 months postpartum in patients who have DVT or PE during pregnancy. Patients receiving this treatment require laboratory testing every 1 or 2 weeks, and the efficacy of anticoagulation may be variable in pregnancy. Low-molecular-weight heparin is considered safe in pregnancy and offers several advantages over unfractionated heparin: decreased bleeding risk, reliable pharmacokinetics, decreased risk of heparin-induced thrombocytopenia, fixed dosages, less frequent dosing, and decreased risk of osteoporosis and thrombocytopenia.[106-108] In patients with a history of DVT or PE, prophylaxis for subsequent gestations is usually recommended.[109-111]

Genitourinary Infections

Urinary Tract Infection

Principles of Disease. Asymptomatic bacteriuria in pregnancy predisposes the patient to development of symptomatic lower and upper tract genitourinary infections, resulting in the U.S. Preventive Services Task Force recommendation to screen for asymptomatic bacteriuria with urine culture in pregnant women at 12 to 16 weeks' gestation or at the first prenatal visit, if later (Grade A recommendation).[112] Uterine pressure exerted on the bladder and ureters, poor emptying of the bladder with voiding, and progesterone-induced smooth muscle relaxation that inhibits ureteral peristalsis appear to contribute to increased risk of infection during pregnancy.

Prenatal screening of patients with asymptomatic bacteriuria in early pregnancy identifies approximately 95% of individuals at risk for subsequent bacteriuria during the pregnancy. Because up to 30% of women who have asymptomatic bacteriuria will have pyelonephritis if they are untreated, treatment of bacteriuria is cost-effective and important.[113]

Clinical Features and Diagnostic Strategies. The pregnant patient who presents with lower urinary tract symptoms (e.g., dysuria, frequency, and urgency) or upper tract symptoms (e.g., fever, malaise, or back pain) should have a pelvic examination and evaluation of an uncontaminated urine specimen (preferably catheterized). There is a predominance of right-sided symptoms during pregnancy, probably the result of increased mechanical forces on the right ureter, but left-sided flank pain or bilateral symptoms may be caused by pyelonephritis. Rarely, urinalysis may yield normal results or cultures may produce negative findings, either because of failure to report lower colony counts or because of complete obstruction of the involved ureter.

The major risk of asymptomatic and lower urinary tract infection is spread to the renal parenchyma. Acute pyelonephritis carries considerable morbidity in pregnancy, including maternal sepsis, permanent renal injury, and premature labor.[113] The risk of prematurity can be minimized by effective treatment and continued monitoring for recurrence. The development of premature labor in the woman who has pyelonephritis is ominous and can be prevented only by aggressive recognition and treatment earlier in pregnancy.

Differential Considerations. Vaginitis, herpes genitalis, chlamydial infection of the urethra, and ovarian torsion can masquerade as urinary tract symptoms. A history of external dysuria (burning at the perineum with urination) suggests herpes or vaginitis. A pelvic examination should be performed to obtain cervical culture specimens and to identify perineal or vaginal causes of dysuria. Appendicitis, cholecystitis, pancreatitis, and liver diseases in pregnancy must be considered in the differential diagnosis of upper urinary tract infection. Back pain may also be a sign of premature labor. Careful evaluation of an uncontaminated catheterized urine specimen is essential to the correct diagnosis.

Management. Patients with asymptomatic bacteriuria or lower urinary tract signs and symptoms should be treated with 7 to 10 days of an antibiotic that is active against usual urinary pathogens and is safe in pregnancy. The most common choices are a cephalosporin, a nitrofurantoin, or a sulfonamide (except during the third trimester). Clinicians should consider factors such as cost, local availability, and side effects in the selection of the best treatment option.[114]

Patients with fever, back pain, and evidence of acute pyelonephritis in pregnancy are usually admitted for intravenous antibiotic administration, although outpatient parenteral therapy can be effective and safe in selected patients.[115] In such cases, aggressive intravenous hydration, obstetric consultation, and urine cultures should be initiated. At least one parenteral dose of antibiotics should be given, with antibiotic coverage guided by known organism susceptibilities in a given hospital. Because the resistance of *Escherichia coli* to ampicillin is considerable in most regions, a cephalosporin is the usual intravenous medication administered. Cultures must be performed to ensure that the original choice of antibiotic was correct, and the patient must have a repeated culture and be observed closely after treatment.

Vaginitis

Bacterial Vaginosis

Bacterial vaginosis (formally known as *Gardnerella* vaginitis or *Haemophilus vaginalis* vaginitis) is an overgrowth of multiple endogenous vaginal bacteria, in some cases producing excessive discharge and vaginal malodor. Prevalence rates for bacterial vaginosis in pregnancy are estimated at 15 to 20%. Bacterial vaginosis is associated with an increased risk of chorioamnionitis, subclinical PID, premature rupture of membranes, fetal prematurity, and postpartum endometritis after vaginal delivery. However, treatment of bacterial vaginosis is directed toward symptomatic relief for the patient and does not necessarily improve fetal outcomes. Management includes a 7-day course of metronidazole or a 7-day course of clindamycin. Intravaginal treatment is not recommended in pregnant patients.[116]

Candida albicans Vaginitis

The incidence of vulvovaginal candidiasis is increased during pregnancy by high levels of estrogen and other steroids. Oral azoles are contraindicated in pregnancy because of an association with adverse fetal outcomes.[117] Treatment with vaginal azoles for 7 days during pregnancy is considered safe, with an estimated 85 to 100% cure rate.[116] Recurrent disease may require a vaginal culture to confirm diagnosis and to identify unusual candidal species (e.g., *Candida glabrata*) that may be resistant to conventional treatment. Longer treatment or treatment of a potential *Candida* reservoir in the patient's partner may also be required. However, there is no association of *Candida* colonization with adverse pregnancy outcomes, and treatment is for relief of symptoms only.[118]

Trichomonas Vaginitis

Trichomoniasis is a sexually transmitted vaginitis caused by a protozoan parasite, *Trichomonas vaginalis*. Of patients who have trichomoniasis, 50% are asymptomatic. Symptoms include vaginal itching, malodorous discharge, and vaginal irritation. Diagnosis is made by direct visualization or protozoans on wet mount. The recommended treatment is metronidazole, a one-time dose of 2 g, for symptomatic patients only.[116] Although trichomoniasis has been associated with increased prematurity, treatment with metronidazole has not been shown to improve fetal outcomes, so clinicians should counsel patients and consider deferment of treatment in asymptomatic pregnant women until after 37 weeks' gestation.[119]

Sexually Transmitted Diseases in Pregnancy

Sexually transmitted diseases are treated in pregnant patients according to the latest Centers for Disease Control and Prevention guidelines. In general, the tetracyclines and quinolones are contraindicated in pregnant patients. Treatment of genital tract infections may be important in both preventing preterm labor and decreasing transmission to the infant.

Chlamydia trachomatis Infection

Chlamydia trachomatis infection is the most common sexually transmitted disease, both in the United States and worldwide. Its prevalence is currently three to five times that of *Neisseria gonorrhoeae* infection. Clinical diagnosis is difficult during pregnancy because cervical mucus is usually cloudy and contains white blood cells, but urine sampling can be done and is equivalent to endocervical sampling in pregnancy infections.[120] Routine chlamydia screening during pregnancy is important to prevent complications of preterm labor and postpartum endometritis, both of which are more common in patients who have chlamydial cervical infections.[119] Chlamydial infections of infants born to infected mothers include conjunctivitis and pneumonitis. Treatment during pregnancy or breast-feeding is azithromycin (single 1-g dose), which improves compliance and decreases gastrointestinal side effects; a 7-day course of amoxicillin is an acceptable alternative.[116]

Herpes Simplex Infection

Herpes simplex virus infections pose a significant risk in pregnancy to both the mother and the newborn. Women who have genital herpes during the third trimester have a 30 to 50% increased risk of transmission compared with women with herpes simplex virus infection in the first trimester (1%). The virus can be transmitted prenatally through transplacental infection or ascending vaginal infection and by vaginal delivery, particularly when herpetic lesions are present. Infections in the neonate often are disseminated or involve the central nervous system, causing significant morbidity and mortality. In the ED, culture of new suspected herpetic lesions of the cervix, vagina, or perineum identifies patients at risk for perinatal complications. Although the risk of oral acyclovir and valacyclovir use in pregnancy is not well known, it is recommended for first-episode genital herpes. Suppressive therapy can reduce the need for cesarean section in women whose first clinical episode of genital herpes simplex occurred during pregnancy but may not eliminate the need for cesarean section in women with recurrent herpes simplex.[121,122] Treatment should be undertaken with obstetric consultation and careful patient monitoring.

Neisseria gonorrhoeae Infection

Gonococcal infection of the cervix occurs during pregnancy in 1% of women. Symptoms are similar to those in nonpregnant women. Salpingitis is rare but may develop during the first trimester from upper genital extension of cervical infection. Some practitioners believe that the incidence of the disseminated infection is increased in pregnant patients because of elevated progesterone levels and increased vascularity in the area of the cervix. Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy, and treatment includes cephalosporins or azithromycin.[116] Treatment of possible coexistent chlamydial infection is recommended for pregnant and nonpregnant women. The major complications of third-trimester gonococcal infection are neonatal gonococcal ophthalmia and sepsis.[116,119]

Upper Genital Tract Infection

Pelvic Inflammatory Disease

PID is very rare in pregnancy and does not occur after the first trimester. Differential diagnosis includes ectopic pregnancy, septic abortion, and appendicitis, all of which are more common. In the patient with suspected infection, smears or cultures for chlamydia and gonorrhea should be performed. Given the risk of endometrial infection in pregnancy and the need to consider other diagnoses, pregnant patients who have suspected PID require hospitalization and intravenous antibiotics.[116]

Chorioamnionitis

Chorioamnionitis is the infection or inflammation of the placenta and fetal membranes. After 16 weeks of pregnancy, the chorioamniotic membranes adhere to the cervical os and may become infected. The risk is increased in women with preterm labor. Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness in a patient past 16 weeks of pregnancy.[123] Leukocytosis can be suggestive of chorioamnionitis but is not diagnostic. Patients should have blood specimens drawn for culture. Vaginal and cervical culture specimens for group B streptococci, *E. coli,* chlamydia, and gonorrhea should also be obtained. Urgent obstetric consultation should be obtained,

www.ketabpezeshki.com 66485457-66963820

and hospitalization for intravenous administration of antibiotics is required. Patients are usually treated with intravenous ampicillin and gentamicin. In addition, a study reported that antenatal steroids may reduce adverse neonatal outcome after preterm birth associated with chorioamnionitis.[124]

KEY CONCEPTS

- There are several types of miscarriages (incomplete, complete, inevitable, and threatened) that must be differentiated because management priorities for these patients differ.
- The history and the physical examination of the patient with ectopic pregnancy are insensitive and nonspecific; therefore pelvic ultrasonography and serum hCG levels are used to evaluate patients deemed to be at risk.
- The major conditions associated with vaginal bleeding in the second half of pregnancy include abruptio placentae and placenta previa. Patient history, physical examination, and results of ultrasonography can be used to distinguish these conditions.
- Appendicitis is the most common surgical emergency in pregnancy, and the clinical presentation of these patients may not be classic, leading to a misdiagnosis rate of 30 to 35% in pregnant patients.
- The treatment of eclampsia includes magnesium sulfate for seizures, reduction of blood pressure, and delivery of the fetus.

ACKNOWLEDGMENT

We thank Dr. Jean Abbott for her work on prior editions of this chapter.

Chapter 179

Chronic Medical Illness during Pregnancy

Kirsten K. Calder

PRINCIPLES OF DISEASE

The physiologic changes that occur in pregnancy may exceed the patient's underlying compensatory mechanisms, resulting in initial symptom onset or rapid decompensation of medical illness during pregnancy. Certain chronic medical conditions also pose a serious threat to the mother's health or result in a poor fetal outcome. Finally, some medical illnesses result in a difficult delivery or the need for special resuscitation measures in the neonate.

The incidence of pregnancy in chronically ill patients is increasing because of improved survival of patients with diseases such as diabetes, epilepsy, renal failure, and various cancers. Also, the demographics of pregnancy are changing in that maternal age at the time of first pregnancy is increasing. Advances in assisted reproduction, including in vitro fertilization and oocyte donation, have made it possible for older women—including those who are postmenopausal—to become pregnant. Older pregnant women experience an increased rate of antepartum and intrapartum complications and are more likely to have comorbid conditions such as cardiovascular disease.

SPECIFIC DISORDERS

Asthma

Asthma is the most common pulmonary problem in pregnancy; it affects up to 8% of gestations, and the prevalence appears to be increasing.[1] The overall effect of pregnancy on asthma seems to be that one third of patients will experience a worsening of the disease, one third will experience improvement, and the other third will remain unchanged.[2] The exact effect of asthma on the fetus is likely to depend on the severity of disease and how well it is managed during pregnancy. Studies show that pregnant asthmatics have good perinatal outcomes in the setting of well-controlled symptoms.[3-6] On the other hand, women with asthma exacerbations during pregnancy are at increased risk for complications, including congenital malformations and preterm delivery[7-9] (see Table 179-1).

Several changes in respiratory physiology during normal pregnancy affect the management of asthma in this context; both the tidal volume and the minute ventilation rise, increasing up to 50% by term. This increase in minute ventilation, or "hyperventilation of pregnancy," lowers the resting P_{CO_2} by an average of 8 to 10 mm Hg to a P_{CO_2} of 32 mm Hg. In response to chronic hyperventilation, there is a compensatory increase in the renal excretion of bicarbonate, with serum levels averaging 19 mEq/mL (19 mmol/L). The net result is a slight respiratory alkalosis, with a serum pH ranging from 7.40 to 7.45. It is important to keep these "normal" values in mind in gauging the severity of an asthma exacerbation in the pregnant patient. Acute asthma exacerbations pose a significant maternal and fetal risk, and the pregnant patient should be managed as aggressively as the nonpregnant patient.[10]

The inhaled beta-agonist agents are generally considered safe in pregnancy (Tables 179-1 and 179-2). As in the nonpregnant patient, inhaled short-acting beta-agonists are first-line agents for acute asthma exacerbations.[3,10] Long-acting agonists (in conjunction with inhaled corticosteroids) are also recommended for maintenance use in patients with moderate or severe disease.[3,10] Selective agonists are preferred because nonselective agents such as epinephrine theoretically decrease uteroplacental blood flow through beta-mediated effects. In addition, although they are safe from a teratogenic perspective, beta-agonists are tocolytics and will usually halt active labor.

Corticosteroids remain the core component for maintenance treatment of asthma in the pregnant patient. In fact, current data support the safety of inhaled corticosteroids,[11] and their chronic use is recommended in all asthmatic patients except those with mild intermittent disease.[3,10] Use of systemic corticosteroids is sometimes necessary on a chronic basis in patients with severe persistent asthma and as a short burst in patients with exacerbations that exhibit inadequate or poor response to initial beta-agonist therapy.

The methylxanthine theophylline has been shown to be safe in pregnancy at therapeutic doses and is an acceptable alternative medication for maintenance therapy for patients with moderate to severe disease.[3,10] There are limited data for cromolyn sodium, but this agent is considered class B (presumed safety) during pregnancy, and its use as an alternative agent is acceptable.[10] Likewise, the leukotriene receptor antagonists (montelukast and zafirlukast) have not been widely investigated. However, an initial small study in pregnant women did not find a significant increase in adverse outcomes, and these medications are also considered class B in pregnancy.[12] Magnesium sulfate has received a good deal of attention in the acute treatment of refractory asthma exacerbations because it has a wide safety profile and potent bronchodilator properties. Although large doses of magnesium have been used for the treatment of eclampsia, at this time there are insufficient data to support routine use of magnesium in this population of patients.

Perhaps the most important tenet of treatment is that if the mother is hypoxic, the fetus is hypoxic as well. In addition, the fetus is more sensitive to hypoxia; thus normal maternal oxygen saturation does not preclude fetal distress. Supplemental oxygen should be administered to all pregnant patients with an acute asthma exacerbation, and assessment of fetal well-being is indicated for viable pregnancies.[3]

Table 179-1 Gestational Effects and Treatment of Medical Illnesses during Pregnancy

MEDICAL ILLNESS	GESTATIONAL CONCERNS	TREATMENT
Asthma	*Fetal:* IUGR, PTD, hypoxia, meconium-stained amniotic fluid, fetal loss *Maternal:* preeclampsia, gestational hypertension, gestational diabetes, hyperemesis gravidarum, need for labor induction	Good prenatal outcomes are seen in well-controlled asthma. Treatment of acute exacerbations is the same as for the nonpregnant patient. Fetal monitoring for exacerbations during the third trimester is recommended even in the absence of maternal hypoxia. Maintenance therapy also is unchanged with the following precautions: Corticosteroids: inhaled agents are preferred, but the oral route may be necessary with severe, persistent disease; patients receiving long-term steroids require "stress dose" hydrocortisone during labor and delivery. Methylxanthines: safe but debatable benefit; use only in refractory disease; reduced clearance during pregnancy may result in maternal toxicity and fetal tachycardia. Leukotriene receptor antagonists: avoid zileuton.
Acute coronary syndrome	*Fetal:* perinatal death, PTD *Maternal:* uterine hemorrhage and abruption (related to use of antiplatelet, antithrombotic, and fibrinolytic agents)	Standard medical therapy is the same as for the nonpregnant patient, although antiplatelet, antithrombotic, and fibrinolytic agents are best avoided when delivery is imminent. Avoid maternal hypotension when nitrates are used; they may result in fetal distress. Avoid beta-blockers in the first trimester (teratogenic). Coordinate definitive care (fibrinolytics vs. percutaneous coronary intervention) with cardiologist.
Valvular heart disease	*Fetal:* perinatal death, PTD *Maternal:* heart failure, thromboembolism, death	Appropriate antithrombotic therapy is indicated for patients with prosthetic valves and atrial fibrillation (see text). Mitral stenosis: diuresis and beta-blockade; avoid volume depletion when diuretics are used; valvuloplasty or open cardiac surgery for severe symptomatic disease; consider early pregnancy termination in women with severe stenosis. Mitral and aortic regurgitation: diuresis in patients with pulmonary congestion; surgical therapy for acute regurgitant lesions. Aortic stenosis: avoid hypotension and the supine hypotensive syndrome; vigorous fluid replacement during delivery; valvuloplasty or open cardiac surgery for severe symptomatic disease; consider early pregnancy termination with severe symptoms despite therapy.
Hypertension	*Fetal:* perinatal death, IUGR, PTD *Maternal:* progression of target end-organ damage, superimposed preeclampsia, abruption, cardiac decompensation	The majority of perinatal complications occur in patients with preeclampsia or secondary causes of hypertension; outcomes are usually good with mild essential hypertension. Fetal cyanide poisoning might develop after several hours of sodium nitroprusside. Avoid prolonged infusions and use as agent of last resort. The most commonly used agents include methyldopa (preferred agent), labetalol, and hydralazine. Avoid beta-blockers in the first trimester as they may cause fetal growth restriction and may also decrease placental blood flow. Avoid angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers.
Iron deficiency anemia	*Fetal:* low birth weight, PTD, low fetal iron stores, fetal loss (with severe anemia) *Maternal:* preeclampsia, high-output heart failure (rare); effects on maternal mortality unclear	Oral iron supplementation is indicated to improve maternal iron stores. Several over-the-counter preparations are available. There is a delay from onset of therapy to increase in serum hemoglobin. Parenteral iron replacement is safe and effective although rarely required. Transfusion is rarely required but is a consideration for fetal well-being in mothers with severe anemia.
Sickle cell anemia	*Fetal:* fetal loss, IUGR, PTD, and premature rupture of membranes *Maternal:* ↑ need for cesarean section, preeclampsia, infection, heart failure, pulmonary infarction, ↑ incidence of painful crises; maternal mortality low with treatment; false-positive Apt and Kleihauer-Betke test results secondary to persistent hemoglobin F	Management of pain crises and infections is the same as for the nonpregnant patient, with rest, hydration, narcotic analgesia, supplemental oxygen, and antibiotics as indicated. Narcotic analgesics should not be withheld, but the need for neonatal respiratory support should be anticipated if delivery is imminent. Prophylactic transfusion is not indicated. Fetal monitoring and assessment of fetal well-being are indicated for viable pregnancies. Chronic maintenance care includes pneumococcal vaccination and supplemental folate. Hydroxyurea has been discouraged during pregnancy, but few adverse fetal effects have been reported in humans.

Table 179-1 Gestational Effects and Treatment of Medical Illnesses during Pregnancy—cont'd

MEDICAL ILLNESS	GESTATIONAL CONCERNS	TREATMENT
Epilepsy	*Fetal:* various congenital malformations associated with AEMs, fetal hypoxia and bradycardia, fetal loss *Maternal:* variable changes in seizure frequency; alterations in AEM levels; increased seizure frequency secondary to voluntary medication noncompliance; abruption, anemia, hyperemesis gravidarum, preeclampsia, possible need for labor induction and cesarean section, premature rupture of membranes	Management of status epilepticus is the same as for the nonpregnant patient. Maintenance therapy should be coordinated by the patient's neurologist (or primary care practitioner) and obstetrician. In general, a single AEM given at the lowest effective dose is recommended. In general, patients with pregravid seizure control with AEM monotherapy may continue their current regimen. There is limited experience with newer AEMs, but these are likely to have a more favorable side effect profile. Folate supplementation (at least 0.4 mg/day) is indicated for patients taking older AEMs. Consider administration of oral vitamin K to the mother during the last month of pregnancy and parenteral vitamin K to the newborn.
Myasthenia gravis	*Fetal:* transient neonatal myasthenia syndrome *Maternal:* variable changes in disease severity; arrest of labor; disease exacerbation in the postpartum period	Management is the same as for the nonpregnant patient. Ventilatory support is the most important aspect of therapy. Note that patients with myasthenia gravis are relatively resistant to depolarizing paralytic agents; higher doses may be required. Pyridostigmine therapy can be continued; intravenous therapy is recommended during labor. Patients receiving maintenance corticosteroids require "stress dose" hydrocortisone during labor and delivery. Plasmapheresis is safe during pregnancy.
Diabetes mellitus: insulin dependent (IDDM), non–insulin dependent (NIDDM), and gestational (GDM)	*Fetal:* congenital malformations; macrosomia; IUGR; fetal loss; neonatal hypoglycemia, jaundice, hypomagnesemia, and hypocalcemia *Maternal:* preeclampsia, "brittle" diabetes, ↑ need for cesarean section; mothers with GDM have increased risk for development of postpartum diabetes	Every attempt should be made to maintain maternal serum glucose concentration of 100 mg/dL. Note that insulin requirements decrease during the immediate postpartum period, and the mother may not need insulin for 24-48 hours after delivery. Insulin therapy, with either intermittent dosing or continuous subcutaneous infusion, is standard care for patients with both IDDM and NIDDM. Management of diabetic ketoacidosis is the same as for the nonpregnant patient with the addition of an assessment of fetal well-being and continuous fetal heart monitoring; blood glucose concentration may be normal or only slightly elevated. GDM is often manageable with diet alone, but insulin therapy may be required when the fasting plasma glucose level remains >105 mg/dL. New data suggest that glyburide may be acceptable, but avoid hypoglycemia.
Hyperthyroidism	*Fetal:* PTD, low birth weight, fetal thyroid dysfunction, fetal loss *Maternal:* preeclampsia, heart failure	Management of thyroid storm is the same as for the nonpregnant patient and includes a search for the underlying precipitant. Therapy for hyperthyroidism in the absence of thyroid storm: Reversal of sympathetic effects: propranolol in standard doses is useful until thyroid hormone synthesis has been blocked by thioamides. Thioamides: both propylthiouracil (PTU) and methimazole at the lowest effective dose are acceptable; PTU is preferred. Surgical therapy: thyroidectomy is useful in refractory cases. Other: avoid iodide if possible; hydrocortisone decreases peripheral conversion of T_4 to the more active T_3 and can be used during pregnancy. Radioactive iodine is absolutely contraindicated.
Hypothyroidism	*Fetal:* congenital malformations, low birth weight, fetal loss, fetal thyroid dysfunction, and goiter *Maternal:* preeclampsia, abruption, postpartum hemorrhage, ↑ need for cesarean section	Maintenance therapy includes levothyroxine 0.15 mg/day. Appropriate treatment prevents adverse obstetric and fetal outcomes. Myxedema coma is rare, but when present, treatment is the same as for the nonpregnant patient.
Tuberculosis	*Fetal:* fetal loss, low birth weight, PTD; fetal and neonatal tuberculosis *Maternal:* preeclampsia; potential for delayed diagnosis and treatment out of concern for the fetus	Positive response to purified protein derivative (PPD)/normal chest radiograph: 6- to 9-month course of isoniazid (starting after the first trimester) for patients with recent conversion (<2 years); patients who have been PPD positive > 2 years may defer treatment until after delivery but should still be offered a course of isoniazid because it is safe in pregnancy. Active tuberculosis: 9-month course (starting immediately) of isoniazid plus rifampin or ethambutol (all three agents in combination recommended by the American Thoracic Society). Multidrug-resistant tuberculosis warrants aggressive therapy without regard to potential teratogenicity. Pyridoxine is indicated for all patients receiving isoniazid.

Table 179-1 Gestational Effects and Treatment of Medical Illnesses during Pregnancy—cont'd

MEDICAL ILLNESS	GESTATIONAL CONCERNS	TREATMENT
HIV/AIDS	*Fetal:* HIV infection, PTD, fetal loss; neonatal drug withdrawal if the mother uses injection drugs *Maternal:* postpartum endometritis, uterine bleeding (in the setting of thrombocytopenia)	Antiretroviral therapy: Highly active antiretroviral therapy (HAART) should be offered to all pregnant patients with HIV infection and viral load > 1000 copies/mL. The HAART regimen should include zidovudine (AZT) to prevent vertical transmission of the virus. There are specific HAART drug-related concerns during pregnancy; decisions about therapy are best made by appropriate specialists. AZT monotherapy is not recommended except in those patients with a low viral load who do not wish to take HAART. In these cases, AZT is appropriate to reduce disease transmission. Cesarean section is recommended with viral load > 1000 copies/mL. Opportunistic infections require standard therapies despite the potential fetal effects.
Syphilis	*Fetal:* congenital syphilis, fetal loss, PTD, IUGR, nonimmune hydrops	Primary, secondary, early latent (<1 year): benzathine penicillin G, 2.4 million units IM × one dose Late latent (>1 year or unknown duration): benzathine penicillin G, 2.4 million units IM weekly × three doses Neurosyphilis: aqueous penicillin G, 2-4 million units IV q4h × 10-14 days, or procaine penicillin G, 2.4 million units IM, and probenecid, 500 mg PO q6h × 10-14 days

AEM, antiepileptic medicine; *IUGR,* intrauterine growth restriction; *PTD,* preterm delivery.

Table 179-2 Drugs Used in the Treatment of Acute Asthma Exacerbations during Pregnancy

PHARMACOLOGIC CLASS	EXAMPLES	DOSAGE	COMMENTS
Inhaled beta-agonists	Albuterol Levalbuterol	2.5-5 mg every 20 minutes 1.25-2.5 mg every 20 minutes	Inhaled beta-agonists first-line therapy May also be administered by metered-dose inhaler Up to three doses in first hour; continuous use in severe exacerbations
Injectable beta-agonists	Epinephrine Terbutaline	0.3-0.5 mg SC (1:1000 or 1 mg/mL) every 20 minutes 0.25 mg SC (1 mg/mL) every 20 minutes	No proven benefit over inhaled dosing Up to three doses in first hour
Systemic corticosteroids	Prednisone Prednisolone Methylprednisolone	Dosage applies to all preparations Initial inpatient therapy: variable dosing; need at least 120-180 mg/day Outpatient burst therapy: 40-60 mg/day for 3-10 days	No benefit of intravenous dosing over oral except in patients with impending respiratory failure who cannot take oral medications
Inhaled anticholinergics	Ipratropium bromide	0.5 mg every 20 minutes	Not first-line therapy; should be used with beta-agonists Consider for use in patients with severe exacerbations
Smooth muscle relaxants	Magnesium sulfate		Limited data on its use for asthma in pregnancy

Modified from National Heart, Lung, and Blood Institute; National Asthma Education and Prevention Program Asthma and Pregnancy Working Group: NAEPP Expert Panel Report. Managing asthma during pregnancy: Recommendations for pharmacologic treatment—2004 update. J Allergy Clin Immunol 115:34, 2005.

Hypertension

Chronic Hypertension and Hypertensive Emergencies

Chronic hypertension is defined as elevated blood pressure that is present before the onset of pregnancy or that begins before the 20th week of gestation. It affects up to 7% of pregnancies and represents a significant source of maternal and fetal mortality and morbidity (see Table 179-1).[13,14] The emergency physician may be required to provide therapy for hypertensive emergencies in patients with chronic hypertension and to differentiate between the various hypertensive disorders of pregnancy (Table 179-3).[13-15]

In the treatment of chronic hypertension in pregnancy, the physician should try to balance the goal of reducing maternal blood pressure with the requirements to maintain cardiac output and to minimize adverse effects for both mother and fetus.[13,14,16,17] Precipitous and marked decreases in blood pressure may significantly diminish uteroplacental blood flow. Treatment of patients with mild to moderate disease does not have an appreciable effect on perinatal outcomes, nor does it reduce the incidence of superimposed preeclampsia. In addition, these patients are likely to have a decrease in blood pressure without pharmacologic agents because of normal physiologic changes that occur in pregnancy, and they are often successfully managed without medications.[13,14,17] On the contrary, patients with more severe hypertension, patients with evidence of end-organ damage, and patients taking more than one pregestational antihypertensive medication probably need maintenance medical therapy (see Table 179-1).[13,17] Lifestyle modification is a potential mode of therapy, but it is unclear whether strict dietary and weight restrictions are appropriate in the gravid patient.[18]

www.ketabpezeshki.com 66485457-66963820

Table 179-3 Hypertensive Disorders of Pregnancy

	CHRONIC HYPERTENSION	GESTATIONAL HYPERTENSION	PREECLAMPSIA	CHRONIC HYPERTENSION WITH SUPERIMPOSED PREECLAMPSIA
Definition	Hypertension* that antedates pregnancy	Hypertension diagnosed after 20 weeks of gestation in the absence of proteinuria or other evidence of preeclampsia	Hypertension that begins after 20 weeks of gestation in association with new-onset proteinuria (>300 mg/24 hr)	Hypertension that antedates pregnancy in association with new-onset proteinuria
	Hypertension diagnosed before 20 weeks of gestation			Sudden increase in proteinuria in a woman with chronic hypertension* and proteinuria before 20 weeks of gestation Hypertension that antedates pregnancy in association with sudden increase in blood pressure
	Comment: rarely, preeclampsia presents before 20 weeks of gestation	*Comment:* may progress to preeclampsia; may also represent previously undiagnosed hypertension		Hypertension that antedates pregnancy in association with decreased platelets or elevated liver transaminases

Modified from Roberts JM, et al: Summary of the NHLBI Working Group on Research on Hypertension During Pregnancy. Hypertension 41:437, 2003; and the National Institutes of Health: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Bethesda, Md, U.S. Department of Health and Human Services.
*Defined as blood pressure > 140 mm Hg systolic or > 90 mm Hg diastolic.

Decisions about maintenance therapy are most appropriately made by the patient's primary care practitioner in conjunction with her obstetrician. However, the emergency physician may be called on to make treatment decisions for patients with severely elevated blood pressure and for patients with superimposed eclampsia. Methyldopa remains the preferred maintenance agent, but nearly all of the major classes of antihypertensive agents are acceptable in the pregnant patient, with the exception of angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers. Diuretics are considered second-line agents because of concerns about plasma volume constriction (see Table 179-1).[13,14,15,17] Hydralazine and labetalol are the agents most commonly used for hypertensive emergencies associated with eclampsia and are also appropriate for such emergencies in the patient with chronic hypertension. Sodium nitroprusside can cause fetal cyanide toxicity after several hours of infusion and is considered a second-line agent (Table 179-4).[13,17]

Patients with chronic hypertension are more likely to have preeclampsia, a situation that results in increased morbidity and mortality compared with either process in isolation. Coexistence of the two disorders should be suspected in the following situations: (1) new onset of proteinuria after 20 weeks of gestation in a patient with known hypertension and (2) pregnant patients with hypertension and proteinuria before 20 weeks of gestation who have thrombocytopenia, increased transaminase levels, or an acute increase in proteinuria or blood pressure (see Table 179-3).[18]

Table 179-4 Antihypertensive Agents for Hypertensive Emergencies

ANTIHYPERTENSIVE AGENT	DOSE	COMMENT
Hydralazine	5 mg IV, then 10 mg IV every 20-30 minutes until target blood pressure is achieved	Consider another agent if inadequate response despite administration of 25 mg
Labetalol	20 mg IV; subsequent dosing with 40 mg, then two doses of 80 mg every 10 minutes until target blood pressure is achieved	Consider another agent if inadequate response despite administration of 220 mg Standard contraindications apply
Sodium nitroprusside	Infusion rates vary; start at 0.25 µg/kg/min	Use only if other agents are not effective; fetal cyanide toxicity is possible after several hours

From the National Institutes of Health: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Bethesda, Md, U.S. Department of Health and Human Services; August 2004. NIH Publication No. 04-5230.

Pulmonary Hypertension

The cardiovascular changes associated with pregnancy and delivery are poorly tolerated in patients with pulmonary hypertension. Data for pregnancy in women with pulmonary hypertension are generally limited to case series, but maternal mortality rates have classically been reported to range from 30 to 56%, depending on the underlying cause (primary pulmonary hypertension, secondary vascular pulmonary hypertension, or Eisenmenger's syndrome). Recent case series suggest that a lower mortality rate is possible in the setting of aggressive monitoring and care, including use of prostacyclin analogues and phosphodiesterase inhibitors.[19,20] Unfortunately, however, a recent literature review shows that mortality remains unacceptably high (17-33%).[21]

The primary goals in treatment of the pregnant patient with pulmonary hypertension are to ensure high right ventricular filling pressures by maintenance of adequate volume status and to obtain early consultation with obstetrics and cardiology services. Pregnancy is not recommended in women with pulmonary hypertension, and those with early gestations should be referred for elective pregnancy termination.

Cardiac Disorders

Acute Coronary Syndromes

Coronary artery disease is rare in pregnant women; a population-based study noted a diagnosis of acute myocardial infarction

www.ketabpezeshki.com 66485457-66963820

(AMI) in up to 6.2 per 100,000 deliveries.[22] Prior mortality rates were reported to be approximately 20%, but more recent studies reveal rates ranging from 5 to 11%.[22-24] Normal physiologic changes of pregnancy, such as increased cardiac output and reduced oxygen-carrying capacity secondary to physiologic anemia, have the potential to exceed the threshold for angina if a fixed coronary artery stenosis is present. Certain conditions are also associated with an increased risk of pregnancy-related AMI, including advanced maternal age, thrombophilia, hypertensive disorders, anemia, diabetes mellitus, and tobacco use.[22,23] A review found that comorbid conditions such as tobacco use and diabetes are relatively common in gravid patients with AMI.[24] AMI can occur anytime during the gestational period but peaks during the last trimester and peripartum period.[22,23] Because increases in cardiac output peak during labor and delivery, maternal mortality from AMI is higher in the intrapartum period than during the antepartum or postpartum period.[23,24]

There are a number of potential causes of AMI in pregnant women. Despite their relatively young age, a review found that only 13% of gravidas with AMI have normal coronary arteries.[24] Other pathophysiologic mechanisms besides atherosclerosis that cause AMI in the pregnant patient include coronary artery dissection, vasospasm, and coronary artery thrombosis in otherwise normal vessels. The relative significance of these lesions varies according to the gestational period. Atherosclerotic disease causes the majority of AMIs in the antepartum period, whereas coronary artery dissection is the most common causative lesion during the intrapartum and postpartum stages.[24] Pulmonary embolus, reflux esophagitis, biliary colic, and aortic dissection are all more common than myocardial ischemia during pregnancy and need to be considered in the differential diagnosis. Unfortunately, some women continue to use illicit drugs during their pregnancy, and it is important to consider cocaine use in the pregnant patient presenting with chest pain.

The diagnosis of acute coronary syndrome is similar to that in nonpregnant patients with certain exceptions. Electrocardiographic changes sometimes occur in normal pregnancies and delivery. These include T wave flattening and T wave inversion (mainly in lead III) and nonspecific ST changes during pregnancy as well as ST depression during labor induction for cesarean section.[24] As a result, additional evaluation may be necessary. Echocardiography is useful in correlation of suspicious electrocardiographic findings with wall motion abnormalities. The enzymatic diagnosis of myocardial infarction is unchanged except during and immediately after delivery, when troponin is preferred to creatine kinase, which rises above baseline during this time. Angiography is appropriate in high-risk patients with acute coronary syndrome but is generally avoided in low-risk and stable gravidas.[24] There have been reported cases of dissection resulting from percutaneous intervention during pregnancy.[24] Radionuclide studies carry a lower radiation risk than does angiography but are also generally avoided in stable and low-risk patients.

Treatment of AMI during pregnancy is similar in most respects to treatment of the nonpregnant patient. Survival of the mother is the primary concern, and therapy to improve maternal outcome should not be withheld. Standard treatment includes antiplatelet agents, nitroglycerin, beta-blockers, and antithrombotic agents. However, there are potential adverse effects of such therapy on the mother and fetus (see Table 179-1), and emergent consultation with a cardiologist is recommended. Regarding antiplatelet agents, aspirin remains the first-line agent. There is limited experience with clopidogrel and eptifibatide, but both have been used successfully and are considered safe from a teratogenic standpoint. Heparin has long been considered the antithrombotic agent of choice in pregnant patients, but newer low-molecular-weight agents, specifically dalteparin and enoxaparin, appear to be efficacious and safe and are deemed appropriate for use.[25] Heparin is preferable for patients in the late third trimester because there is a more predictable response to protamine sulfate should labor begin.

Experience with thrombolytic therapy in pregnancy is extremely limited; most experience has occurred in the setting of stroke, prosthetic valve thrombosis, and massive pulmonary embolism.[26,27] The majority of pregnant patients receiving tissue plasminogen activator have had favorable maternal and fetal outcomes, but most were being treated for indications other than AMI.[26] Reported adverse effects have included maternal hemorrhage, maternal death, placental abruption, preterm delivery, fetal death, and fetal intracranial hemorrhage, although the causal relationship in many of these cases is unclear because neither tissue plasminogen activator nor streptokinase crosses the placenta. Because thrombolytic therapy precludes major surgery and epidural anesthesia in the hours to days immediately after administration, the emergency physician must carefully consider whether to use these agents in pregnant women who are close to term, especially if the need for cesarean delivery is anticipated. In addition, the use of thrombolytics in coronary artery dissection is not advised. Because of the lack of data and potential risks of fibrinolytics in gravidas, emergent percutaneous intervention is the treatment of choice for definitive management of AMI.[24,28]

In the setting of peripartum AMI, labor should be conducted with continuous monitoring of both the mother's hemodynamic status and fetal well-being. There are benefits and risks of both vaginal and operative delivery. Cesarean section avoids prolonged exertion by the mother but subjects the patient to general anesthesia if use of antithrombotic agents precludes epidural catheter placement. In addition, surgical delivery places the patient at risk for typical postoperative complications, such as infection, hemorrhage, and thromboembolism. Therefore, assisted vaginal delivery is preferred unless there is an obstetric reason for cesarean section.[24] Resolution of angina may occur during the postpartum period as physiologic demands lessen, but its occurrence during pregnancy merits a complete cardiac evaluation for acute coronary syndrome.

Valvular Heart Disease

Maternal valvular heart disease can be congenital or acquired and is one of the leading causes of nonobstetric death. Acquired valvular disease is mainly the result of rheumatic fever and endocarditis. In the United States, most cases of significant congenital heart disease are identified and corrected surgically before puberty. The ability of patients to tolerate pregnancy without significant adverse effects depends on the type and severity of the lesion. Mild to moderate lesions (New York Heart Association classes I and II) are often associated with good outcomes. On the other hand, mitral stenosis (beyond class I), advanced aortic stenosis, aortic and mitral lesions associated with moderate to severe ventricular dysfunction or pulmonary hypertension, and mechanical prosthetic valves requiring anticoagulation can result in significant maternal mortality and require directed therapy (see Table 179-1).[29]

Mitral Stenosis

Mitral stenosis is the most commonly encountered valvular lesion in pregnancy and is also the most important lesion to detect in early pregnancy because maternal mortality is not insignificant.[30] The increased resting heart rate and stroke volume in normal pregnancy increase the pressure gradient across the mitral valve. The result is high left atrial pressures, pulmonary vascular congestion, and the symptoms and physical findings typical of left ventricular failure. Patients may also develop atrial dysrhythmias that have the potential to decrease cardiac output and worsen

www.ketabpezeshki.com 66485457-66963820

symptoms.[30] The likelihood of maternal symptoms and worsening of cardiovascular status is directly related to the severity of disease. Pregnancy in women with mild mitral stenosis is generally well tolerated.[30]

In patients with symptomatic mitral stenosis, treatment is aimed at reduction of the plasma volume and slowing of the heart rate (see Table 179-1). Surgical intervention is indicated in patients with refractory symptoms despite optimal medical management and in patients with pulmonary hypertension. The preferred procedure is percutaneous balloon valvotomy, which is associated with good maternal and fetal outcomes when it is performed in experienced centers.[28-30]

Aortic and Mitral Regurgitation

In most cases, chronic regurgitant lesions are well tolerated during pregnancy and may even improve as the reduced systemic vascular resistance of pregnancy allows more forward and less regurgitant flow. In addition, this effect is aided by the increase in heart rate and shortened diastole that occur in pregnancy.[28-30] When necessary, medical therapy consists of diuresis, digoxin, and vasodilators. Patients with acute mitral regurgitation due to ruptured chordae do not fare as well and may require surgical therapy.[28-30]

Aortic Stenosis

Symptomatic aortic stenosis during pregnancy usually occurs in the setting of a congenital bicuspid valve.[28,29] Patients with mild to moderate aortic stenosis tend to have uncomplicated pregnancies,[30,31] and conservative management is often possible. Severely symptomatic patients may need percutaneous valvotomy in an experienced institution, although this procedure is risky for both the mother and the fetus.[28,29]

Prosthetic Heart Valves

Anticoagulation for the pregnant patient with a prosthetic heart valve is complicated. Warfarin is considered to be contraindicated during weeks 6 through 12 of gestation, although the risk of embryopathy is likely to be low when the dose is less than 5 mg/day.[28,29] In addition, because warfarin crosses the placenta, there is a risk of fetal bleeding. If warfarin is used after the first trimester, it should be replaced by a heparin compound several weeks before anticipated delivery.[29,32] Neither unfractionated heparin (UFH) nor low-molecular-weight heparin (LMWH) crosses the placenta or is teratogenic, but there are problems with their use in pregnancy. The response to UFH is more unpredictable in the pregnant patient, and aggressive dosing with frequent monitoring of the activated partial thromboplastin time is indicated.[32] LMWH is an acceptable alternative to UFH in pregnant patients with thromboembolic disease, but there are still only limited data on its use in the gravida with a mechanical valve.[29] In addition, there is an increased incidence of valve thrombosis in the setting of inadequate dosing and monitoring of anticoagulation.[32] If the practitioner elects to use LWMHs, frequent monitoring of anti-Xa levels is recommended with the goal of achieving a level of approximately 1.0 unit/mL 4 hours after injection.[29,32] In addition, intravenous UFH is substituted for LMWH 24 hours before delivery in anticipation of epidural or spinal anesthesia.[32]

Hematologic Disorders

Anemia

By far the most common medical complication of pregnancy is anemia. The physiologic adaptations to pregnancy include expansion of plasma volume in excess of the increase in red blood cell (RBC) mass. This results in the dilutional, physiologic anemia of pregnancy, with nadir hemoglobin occurring near the beginning of the third trimester. Any type of anemia can complicate pregnancy, but the three types most commonly involved are iron deficiency, folate deficiency, and sickle cell hemoglobinopathy.

Iron Deficiency Anemia

Iron deficiency anemia is common, occurring in approximately 20 to 25% of pregnancies in industrialized countries.[33] Apart from chronically low or marginal iron stores in many women, diversion of maternal iron to the fetus for development of its own RBCs and iron stores and increased maternal demand for iron exacerbate the deficiency during pregnancy. Pregnant patients are also subject to other causes of iron deficiency anemia, such as malnutrition, chronic underlying disease, and blood loss from the gastrointestinal or genitourinary tracts.

Anemia in pregnancy is defined by the World Health Organization as a hemoglobin concentration of less than 11 g/dL (110 g/L). Because of physiologic dilution, this level may be slightly lower after the 25th week of gestation. The risks of adverse pregnancy outcomes (see Table 179-1) have been noted to be related to the severity of the anemia. This generally is manifested as a proportionate increase in the risk of preterm delivery and low-birth-weight babies for women with mild to moderate anemia.[33-35] Severe anemia (<6 to 7 g/dL or 60 to 70 g/L), especially occurring early in pregnancy, is associated with even higher rates of preterm delivery and low birth weights as well as increased fetal mortality, abnormal fetal oxygenation, premature rupture of membranes, gestational hypertension, and reduced volume of amniotic fluid.[36,37]

It is currently recommended that all pregnant patients be screened for iron deficiency anemia.[36] The diagnosis is most accurately made in the very early stages of pregnancy because serum ferritin, the most sensitive and specific (and preferred) test, is affected by the dilutional effect of increased plasma volume occurring later in pregnancy. After the first trimester, other blood tests performed in combination may be necessary. The use of RBC indices is not a reliable screening tool because microcytosis and hypochromia are not reliably present in pregnant patients. Other supporting laboratory evidence includes low plasma iron levels, increased free erythrocyte protoporphyrin, and elevated total iron-binding capacity.

Iron supplementation with non–enteric-coated preparations is recommended to increase maternal iron stores (see Table 179-1) in women with iron deficiency,[36] even though it remains unclear whether such therapy improves perinatal outcomes.[38] Patients with an uncomplicated physiologic anemia who are not iron deficient can be expected to have good obstetric outcomes without therapy and do not require treatment. The use of prophylactic supplementation in women with normal hemoglobin levels (>11 g/dL or 110 g/L) and normal iron stores (ferritin > 20 mg/dL or 20 μg/L) to prevent anemia in late pregnancy remains controversial. One randomized controlled trial found that iron supplements for such women before 28 weeks of gestation did not reduce the prevalence of preterm delivery or development of anemia later in pregnancy but did result in a decreased incidence of low-birth-weight infants.[39] Another trial noted no effect on iron status but found that the incidence of both preterm delivery and low birth weight was reduced in women receiving prophylactic iron.[40] On the other hand, a more recent randomized controlled trial found that nonanemic women receiving oral iron supplementation were more likely to have infants small for gestational age as well as hypertension during gestation.[41] Other investigators have noted that pregnant patients with hemoglobin values typically considered "normal" in the nongravid patient have an increase in adverse outcomes, and the practitioner should consider that gravid patients with hemoglobin values of 13 to 15 g/dL (130 to 150 g/L) have inadequate expansion of their plasma volume.[42]

www.ketabpezeshki.com 66485457-66963820

Folate Deficiency Anemia

Folate deficiency is one of a number of causes of megaloblastic anemia, a condition characterized by abnormal DNA synthesis and ineffective RBC production. The incidence of folate deficiency in pregnancy is low in developed countries but remains higher in other populations. The risk for development of folate deficiency is increased in patients with multiple gestations, short interpregnancy intervals, preexisting malnutrition, hyperemesis gravidarum, malabsorption syndromes, alcoholism, and diets lacking green leafy vegetables and animal protein.[36,43] Use of certain antiepileptic medications also places women at increased risk for deficiency.

Iron deficiency and folate deficiency anemias often coexist, making the peripheral blood smear difficult to interpret. Measurement of serum and RBC folate levels is indicated in cases of suspected folate deficiency, but both have limitations. Serum folate is noted to exhibit a rapid response to folate intake, and low levels may normalize within days after a folate-rich meal. Serum folate is also affected by the hemodilution of pregnancy. RBC folate levels are more static and are indicative of folate status several months before analysis. RBC folate levels may be misleading in more acute cases and are affected as well by the increase in RBC production that occurs in pregnancy.

As is the case for iron deficiency, effects on the fetus depend on the degree of anemia; the most significant complications are neural tube defects (NTDs). Folate supplementation reduces the risk of NTDs,[44,45] and oral folate supplementation with 0.4 mg daily is routinely recommended for all women during pregnancy and before conception as the requirement for this micronutrient increases during gestation.[36] The American College of Obstetricians and Gynecologists recommends 1.0 mg for those women who have a known pregnancy-related deficiency of folate.[36] Women at higher risk for NTDs (e.g., NTDs in prior pregnancy) are advised to take much higher doses of folate at 4 mg daily under the close supervision of their obstetrician.[46]

Sickle Cell Anemia

Sickle cell disease (SCD) is one of the major sources of maternal and fetal complications in the United States. The details of the pathophysiologic mechanism and genetics of SCD are discussed in Chapter 121, but it is useful to review the most common phenotypes that affect pregnancy. The sickle gene can be homozygous (hemoglobin SS or SCD), and this form of the disease is responsible for most pregnancy complications. The sickle gene can also be heterozygous with normal hemoglobin A (sickle cell trait or hemoglobin SA), in which case symptoms are rare except under extreme environmental conditions. The hemoglobin S can also be heterozygous with a large number of abnormal hemoglobins, such as hemoglobin C, several variants of thalassemia, and other rare hemoglobin variants, and each variant has its own complication profile. Of these, the most relevant in terms of pregnancy complications is hemoglobin SC.

Patients with SCD are subject to many chronic medical problems secondary to a variety of pathophysiologic mechanisms, including sickling of RBCs, anemia, immunosuppression caused by autosplenectomy, and repeated transfusion. Median life expectancy is in the fifth decade for both sexes affected by SCD, and female fertility is generally unaffected, so it is likely that the emergency physician will encounter pregnant patients with the disease. Maternal complications are common in patients with SCD and include preterm labor, eclampsia, premature rupture of membranes, maternal infections, more frequent pain crises, thrombosis, and increased need for cesarean delivery.[47-52] Despite these complications, the maternal mortality rate is less than 1% with current treatment.[48,49,51,52]

SCD also results in adverse effects on the fetus (see Table 179-1).[47] Placental infarction and insufficiency are common, and the incidence of small-for-gestational-age and low-birth-weight infants is significantly increased in SCD pregnancies compared with normal controls.[48-51,53] The reported perinatal mortality rate varies but is low in the setting of appropriate maternal and neonatal care.[49,50,52]

Management of SCD during pregnancy is similar to that of the nonpregnant patient (see Table 179-1). Folate supplementation is standard even in the nonpregnant state because of the increased turnover of RBCs, and the recommended daily dose of folate increases to 4 mg daily during pregnancy.[47] The use of supplemental iron and transfusion is controversial because of the potential for iron overload. The need for therapy is best determined by the appropriate specialists after a complete analysis of relevant hematologic parameters. Transfusion or exchange transfusion is generally reserved for patients with symptomatic anemia, cardiopulmonary instability, acute chest syndrome, intrapartum hemorrhage, and preeclampsia and possibly for patients with increasingly frequent pain crises. It is also used preoperatively for anticipated blood loss in patients undergoing cesarean section.[49] In general, the goal with transfusion or exchange transfusion is to lower the percentage of hemoglobin S to 40% and to achieve hemoglobin values of approximately 10 g/dL (110 g/L).[47] Hydroxyurea is not recommended for use in pregnancy because of potential teratogenicity.[47]

Neurologic Disorders

Epilepsy

Epilepsy is the most common neurologic complication of pregnancy but remains relatively rare, affecting less than 1% of all gestations. Epilepsy refers to a broad spectrum of seizure disorders that range from relatively benign and infrequent seizures to a disabling condition with daily, poorly controlled generalized convulsions; therefore, care is individualized. Management of epilepsy during pregnancy entails balancing the risk of increased frequency and duration of seizures to both the mother and the fetus against the teratogenic risks of antiepileptic medications (AEMs).

The effect of pregnancy on epilepsy is variable. Most (50-76%) epileptic patients experience no change in their seizure frequency, whereas approximately 15% experience more frequent seizures.[54-56] A decrease in plasma drug concentrations is expected with certain AEMs, such as phenytoin, lamotrigine, oxcarbazepine, and levetiracetam.[54] This results from a number of potential pregnancy-related physiologic changes, including increased plasma volume, decreased protein binding, and increased renal clearance. In addition, some patients engage in voluntary noncompliance with medications to avoid teratogenic effects on the fetus.

Although gravid patients with epilepsy may be at increased risk for cesarean section, postpartum hemorrhage, and other adverse outcomes (see Table 179-1),[57] the primary complication in these pregnancies is congenital malformations.[56] Of primary concern is the risk for NTDs, facial clefts, and cardiac anomalies with the older generation agents: valproate, carbamazepine, and phenytoin. There is a twofold or threefold increase in the incidence of serious congenital malformations in offspring of epileptic mothers taking these agents. The risk is greatest with valproate and is also increased with AEM polypharmacy.[55,56,58,59] Of all the older agents, carbamazepine appears to be the safest for use as monotherapy.[55,56,58] Controversy exists as to whether infants of epileptic patients not taking AEMs have an increased incidence of congenital malformations compared with the general population. Studies comparing these infants with infants born to mothers without epilepsy noted a similar incidence of malformations.[58] Data are limited, but preliminary results suggest that the rate of congenital malformations with the newer agents lamotrigine and levetiracetam is similar to

www.ketabpezeshki.com 66485457-66963820

that in the general population, and these agents are being used with increased frequency in gravid patients.[59-62]

Care should be provided by specialists in high-risk obstetrics and neurology disciplines. However, emergency physicians may be forced to confront this problem in several clinical scenarios: the pregnant patient with a first-time seizure or status epilepticus and the patient with epilepsy who is found to be pregnant.

New-Onset Seizure

Pregnant patients may seek treatment for idiopathic new-onset seizures; however, drug toxicity or withdrawal, head injury, meningitis, stroke, and eclampsia should be considered possible causes. The most important of these is eclampsia. Patients in the immediate postictal phase often have hypertension resulting from increased sympathetic neural activity, and even those with normal pregnancies may have mild edema of the lower extremities. Consequently, urinalysis is indicated to search for proteinuria, which may be the only differentiating factor in the initial assessment of these patients. After a period of observation, elevated blood pressure in the noneclamptic patient will likely revert to normal. If the patient remains hypertensive or has other signs of eclampsia, magnesium sulfate and other agents are indicated to prevent further seizures and to control blood pressure. In patients who do not have signs of eclampsia, investigation of the cause of the seizure should proceed as with the nonpregnant patient.

Status Epilepticus

Any potential cause of seizure, including eclampsia, may result in status epilepticus. Despite this, status epilepticus in pregnancy is relatively rare, and limited data are available about its occurrence and therapy. Observations from the European Epilepsy Pregnancy Registry note that status epilepticus may occur at any time during gestation and even at delivery. It may also occur in patients who have been seizure free throughout their pregnancy, and no specific risk factors for its occurrence have been identified.[54] Older reports noted a high fetal and maternal mortality, but recent data support a much lower complication rate.[54]

The risk of untreated status epilepticus to both the mother and the fetus clearly outweighs the potential for adverse teratogenic effects, and standard resuscitative measures as well as drug therapy are indicated. Continuous fetal monitoring should be instituted as soon as possible and the mother positioned in the left lateral decubitus position to avoid the supine hypotensive syndrome.

Pregnant Epileptic Patient

Patients with epilepsy coming to the emergency department for unrelated reasons may be found to be pregnant. Although no immediate change in their therapeutic regimen needs to be made, these patients should be advised of the potential risk of AEMs in pregnancy and be referred to appropriate specialists. Unintentional pregnancy is seen even in patients taking oral contraceptives because AEMs can cause increased clearance of these medications, thereby reducing their efficacy.

There are significant obstetric complications related to prolonged seizure activity, and long-term treatment with an AEM for most patients with seizures is warranted (see Table 179-1). Patients who have nonconvulsive seizure disorders or who are seizure free for a sufficient period before conception are candidates for nonpharmacologic observation, but this decision should be deferred to the patient's primary physician or neurologist. Because phenytoin, carbamazepine, valproate, and possibly other AEMs interfere with folate metabolism, oral supplementation with at least 0.4 mg/day is recommended for all women of childbearing age taking these drugs as it may have some efficacy in preventing malformations associated with these agents.[63] Enzyme-inducing AEMs such as carbamazepine, phenytoin, and phenobarbital have been reported to cause neonatal vitamin K deficiency and hemorrhagic complications. However, results from a prospective study of 667 neonates in 662 women taking enzyme-inducing AEMs (none of whom received antenatal vitamin K) indicate that the actual risk of hemorrhage is low and without significant relationship to AEM use.[64] The American Academy of Neurology and the American Epilepsy Society note that there is inadequate evidence to determine a definitive relationship between AEM use and neonatal hemorrhage.[63]

Multiple Sclerosis

Multiple sclerosis (MS) affects approximately 400,000 Americans and is twice as common in women as in men. The peak age at onset is 20 to 35 years, which overlaps peak childbearing years. The disease is characterized by intermittent episodes of central nervous system demyelination with consequent neurologic impairment that follows a relapsing-remitting course. Progressive neurologic deficits and permanent disability develop in certain patients.

The impact of pregnancy on the course of MS has been closely studied in various cohorts of women, and a pattern has emerged. As in other autoimmune diseases, the frequency and severity of exacerbations of MS improve because of the immunosuppressant effects of pregnancy. This effect is most pronounced in the third trimester. During the 3 months after delivery, the rate of relapse increases and then returns to the pre-pregnancy baseline.[65] The risk of postpartum relapse is increased in those women with relapses during the pre-pregnancy year and during pregnancy. Relapses are also more likely in MS patients with higher disability at the time of pregnancy onset. On the other hand, it does not seem that postpartum relapses are related to the duration of disease or the total number of relapses before conception.[65] In addition, pregnancy does not appear to have any significant long-term adverse effects on disease progression.[65] In fact, pregnancies occurring after onset of MS may confer a protective effect in regard to disease course.[66]

MS patients with disease exacerbation are often treated with immunomodulators such as intravenous immune globulin (IVIG), corticosteroids, and interferon beta. Although concerns exist about the use of interferon during pregnancy, small studies in gravid patients have shown that use of IVIG during pregnancy and the postpartum period is safe and may decrease the relapse rate.[67-69] Likewise, the use of intermittent steroids in the postpartum period may decrease the likelihood of disease relapse.[70]

Maternal relapse rate is unaffected by epidural anesthesia,[65] and decisions about anesthesia should be based solely on obstetric considerations. Labor may be complicated by fatigue and uncoordinated voluntary motor activity in pushing, and MS patients may be more likely to require assisted vaginal delivery.[71] These pregnancies may also be at increased risk for preterm delivery and small-for-gestational-age infants.[72] In general, however, pregnancies in the setting of MS have outcomes similar to those in unaffected patients.[71]

Spinal Cord Injuries

Because spinal cord injury (SCI) occurs mainly in young people and usually does not impair fertility, there is a relatively large population of paraplegic and quadriplegic patients who become pregnant. Although many of these pregnancies are uneventful, these patients are at risk for certain complications.

The increased coagulability of pregnancy combined with chronic immobilization results in an increased incidence of thromboembolic disease.[73] The incidence of urinary tract infection is also markedly increased as a result of neurogenic changes and the need for catheterization.[73] Infections are even more likely during pregnancy[74] and may progress to pyelonephritis, with the

www.ketabpezeshki.com 66485457-66963820

subsequent increased risk of fetal loss, prematurity, and maternal sepsis.

A unique problem in the patient with SCI is the detection of the onset of labor, which may be painless and precipitous. Patients with spinal cord lesions below T10 to T12 have an intact uterine nerve supply and will experience labor pains; however, with lesions above T10, labor may be imperceptible or experienced as only mild abdominal discomfort.[73] In addition, up to 85% of patients with high lesions (above T5 to T6) experience potentially life-threatening autonomic dysreflexia.[75] This is manifested as severe paroxysmal hypertension, headache, tachycardia, diaphoresis, piloerection, mydriasis, and nasal congestion. Because the response is not specific to labor and may be precipitated by distention of bowel or bladder, other causes may need to be pursued as well. Pregnant patients with SCI who have these symptoms should be assessed for cervical dilation and have uterine contractions monitored. Emergency department treatment is directed at restoration of normal blood pressure with standard agents. Definitive therapy is with regional anesthesia. Both spinal anesthesia and epidural anesthesia obliterate and prevent this response and should be used as soon as possible during labor for all women with SCI.[75] Because of the difficulty in detecting labor, pregnant patients with SCI are sometimes admitted for observation near term.

Myasthenia Gravis

Myasthenia gravis is a rare disorder in which autoimmune destruction of the postsynaptic cholinergic receptor results in profound muscle fatigability. Treatment with cholinesterase inhibitors can supply additional acetylcholine to achieve virtually normal muscle contractility but should be titrated to avoid precipitation of a cholinergic crisis. Adjustments in medication dosing are frequently required to preserve this balance.

The effect of pregnancy and the postpartum state on myasthenia gravis is unpredictable in the individual patient, but overall approximately 25 to 40% of patients experience exacerbation of disease, with the remainder having improvement or no change in disease severity.[76-78] Several important pregnancy complications are associated with myasthenia gravis. Because of weight gain, anemia, and other physiologic adjustments of pregnancy that may result in fatigue, the distinction between normal pregnancy symptoms and myasthenia may be difficult. Most deliveries are accomplished vaginally without complication in adequately treated patients; assisted and surgical delivery in these women is indicated mainly for obstetric reasons rather than for specific myasthenia-related care.[76,77,79]

Up to 30% of neonates born to mothers with myasthenia gravis have a transient neonatal myasthenic syndrome through placental transport of acetylcholine receptor antibodies.[77] The risk of neonatal myasthenia gravis is decreased in those infants born to mothers who have undergone thymectomy.[77,80] Onset of neonatal myasthenia is typically within the first hours of life but may be delayed by a period of days. Manifestations include poor feeding and suck, diminished reflexes, hypotonia, and respiratory failure. As in adults, the symptoms respond to cholinesterase inhibitors, but treatment should be done in an intensive care unit setting. The duration of the syndrome depends on its severity; severely affected infants sometimes require therapy for several months.[77]

Fortunately, myasthenic crises during pregnancy are rare.[77,78] When exacerbations do occur, treatment is no different from treatment of nonpregnant patients (see Table 179-1). Assessment of pulse oximetry, forced vital capacity, and arterial blood gas parameters will guide respiratory therapy. For patients presenting with weakness, an edrophonium (Tensilon) challenge test to distinguish myasthenic from cholinergic crisis is appropriate after initiation of appropriate ventilatory support. Standard medical treatment is continued during labor and delivery to maximize motor strength. Epidural anesthesia is also recommended to reduce pain and fatigue. Sedatives and other agents that increase fatigue are best avoided during this time. The physician should be aware that 30% of patients experience an exacerbation during the postpartum period as the protective immunosuppressant effect of pregnancy dissipates.[77] In addition, puerperal infections place the patient at risk for disease exacerbation and warrant aggressive therapy.[77]

Renal Disorders

Several alterations in renal hemodynamics occur during pregnancy. Both the glomerular filtration rate and effective renal plasma flow increase by 30 to 50% compared with the nonpregnant state. Because no substantial alterations are present in the production of creatinine or urea nitrogen, levels of these solutes decrease from low normal nonpregnant values of 0.7 and 12.0 mg/dL (53.38 μmol/L and 4.28 mmol/L) to 0.5 and 9.0 mg/dL (38.13 μmol/L and 3.21 mmol/L), respectively. Thus blood urea nitrogen and creatinine levels considered normal in nonpregnant women (creatinine 0.8 mg/dL or 61 μmol/L and blood urea nitrogen 12 mg/dL or 4.28 mmol/L) indicate underlying renal impairment and warrant further investigation.

The primary factors that determine how renal disease affects pregnancy outcome are the degree of underlying dysfunction and the presence of associated hypertensive disorders. In general, patients with mild insufficiency (creatinine $<$ 1.4 mg/dL or 106.76 μmol/L) and no hypertension can expect good pregnancy outcomes and preserved renal function. On the other hand, patients with moderate to severe renal dysfunction have a much higher risk of further decline in renal function as well as adverse obstetric outcomes, including preeclampsia, placental abruption, fetal loss, preterm delivery, low birth weight, polyhydramnios, and increased need for cesarean section and neonatal intensive care.[81-87] Worsening of underlying renal function is more likely in patients with decreased glomerular filtration rate who also have associated proteinuria or hypertension.[84] Because worsening renal function is manifested by hypertension and proteinuria, differentiation from preeclampsia can be difficult. In this setting, it is best to treat the patient for presumed preeclampsia with the caveat that magnesium administration be performed judiciously on the basis of serum magnesium levels.

Pregnant women with chronic renal failure require aggressive and timely management to optimize their chances for a successful gestation without causing further deterioration in renal function. Baseline renal function studies are done early in pregnancy and then reassessed every 4 to 6 weeks. Evidence of renal function deterioration or the development or exacerbation of hypertension warrants admission for specialized inpatient care. Hemodialysis is indicated for creatinine levels above 3.5 to 5 mg/dL (266.91 to 381.3 μmol/L). Pregnancy in women who are already dialysis dependent has been associated with poor outcomes, and pregnancy has previously been discouraged in this population of patients. However, studies including small numbers of women have noted live birth rates approaching 60 to 85% when mothers receive specialized prenatal care.[82,85,86] Such care includes correction of anemia, appropriate antihypertensive therapy, and more aggressive dialysis with more frequent or prolonged sessions.[81,86,88]

Metabolic and Endocrine Disorders

Diabetes

Three types of diabetes are involved in pregnancy: type 1, or insulin-dependent diabetes mellitus (IDDM); type 2, or non–insulin-dependent diabetes mellitus (NIDDM); and gestational diabetes mellitus (GDM). Although NIDDM is sometimes considered a more benign form of disease, the risk of malformations is

www.ketabpezeshki.com 66485457-66963820

the same for both NIDDM and IDDM.[89] Maternal and fetal complications relate to inadequate glycemic control as well as to the presence of vascular complications or severe renal insufficiency more than to the type of diabetes. All pregnant patients with diabetes are considered "brittle" and require regular follow-up by appropriate specialists. In addition, all patients, including those with GDM, should perform routine self-monitoring of glucose concentration.

Maternal Complications

The physiology of glucose regulation during pregnancy is complex. During the first half of gestation, some patients have an increased sensitivity to insulin,[90] although this is not a universal finding and the change in insulin requirements in early pregnancy may be variable. In addition, hormonal changes of pregnancy combined with emesis, increased use of glucose by the placenta and fetus, and decreased hepatic glucose production predispose the gravid diabetic to more rapid onset of hypoglycemia. During later gestation, there is progressive insulin resistance that peaks during the third trimester and then falls again during labor and the immediate postpartum period. Obesity and underlying insulin resistance in NIDDM may exacerbate hyperglycemia during pregnancy.[91] Pregnancy also predisposes to ketosis, and this effect is exacerbated in the setting of emesis. Specific adverse pregnancy-related outcomes are more common and include stillbirth, preeclampsia, preterm delivery, and the requirement for cesarean delivery.[92-94]

The effects of pregnancy on underlying diabetes vary by the organ system. The data are limited, but pregnancy is not advised for diabetic patients with significant coronary artery disease because of the cardiovascular demands of pregnancy and the high mortality of AMI during pregnancy.[92] Patients with diabetic nephropathy are at increased risk for preeclampsia and the subsequent requirement for preterm delivery.[91,92] The renal effects of pregnancy depend on the severity of underlying disease. Patients with mild to moderate renal dysfunction do not seem to experience permanent disease progression. On the other hand, women with more severe renal dysfunction are at increased risk for progression of their nephropathy.[91,92] Retinopathy may worsen acutely during pregnancy, especially in patients with high hemoglobin A_{1c} (HbA_{1c}) levels, hypertension, nephropathy, and active nonproliferative or proliferative retinopathy.[91,95] Laser therapy of preexisting retinopathy is recommended before conception as well as in pregnant patients with severe disease.[91,92,95] Autonomic neuropathy does not accelerate during pregnancy, with the exception of a possible increase in symptomatic severity of gastroparesis,[91] and the combination of hyperemesis gravidarum and gastroparesis often causes problems. Frequent vomiting results in dehydration and inadequate intake of nutrients that can cause hypoglycemic episodes if the insulin dosage is not adjusted accordingly.

Diabetic ketoacidosis (DKA) occurs in up to 9% of diabetic patients during pregnancy and may be the initial presentation of diabetes. DKA is most commonly seen in patients with IDDM but also complicates pregnancies in women with NIDDM and GDM.[91,92,96] Common precipitating events include the typical factors seen in nonpregnant patients, such as insulin noncompliance and infection. Other pregnancy-specific factors are increased insulin resistance, hyperemesis, use of beta-mimetic medications for tocolysis, and use of corticosteroids to hasten fetal lung maturity. The serum pH may be deceptively normal in a pregnant patient with DKA because the initial pH tends to be higher in pregnancy as a result of physiologic hyperventilation. In addition, serum glucose concentration may be normal or only moderately elevated, and screening for DKA is indicated in gravid diabetics with vomiting or with persistent hyperglycemia.[91,96] Maternal mortality is rare in appropriately treated DKA. Fetal mortality rates are relatively high, ranging from 10 to 35%.[92]

Fetal Complications

Diabetes has many deleterious effects on the fetus (see Table 179-1). The rate of congenital malformations in patients with prepregnancy diabetes is increased threefold or fourfold compared with the nondiabetic population, with anomalies being more likely in pregnancies with poor glycemic control.[91,92,97-99] Glucose crosses the placenta, and prolonged fetal exposure to maternal hyperglycemia induces fetal pancreatic hyperplasia and high insulin production. Elevated insulin levels in turn promote fetal growth, resulting in macrosomia and the need for cesarean section. Conversely, preeclampsia and placental infarction secondary to vascular disease may result in impaired fetal development and stillbirth.[94] After delivery, continued high insulin secretion in the absence of a maternal glucose supply results in a significant rate of neonatal hypoglycemia. Because these infants are more likely to be preterm, hyperbilirubinemia and respiratory problems are also more frequent.[92,93]

Management

Treatment of NIDDM and IDDM requires individualized and carefully adjusted insulin administration with the goal of maintaining strict glycemic control while avoiding hypoglycemia. Several studies suggest that sulfonylureas and metformin are safe and effective in pregnancies complicated by GDM,[100,101] but experts recommend that NIDDM patients taking oral agents be transitioned to insulin during pregnancy.[91,92,102] Ideally, HbA_{1c} values should not be higher than 6%[91,92] (see Table 179-1). Frequent self-monitoring is recommended, and these patients should also have frequent office visits with their practitioner throughout the duration of pregnancy. It is preferable to achieve glycemic control as manifested by a normal or nearly normal HbA_{1c} level before conception to minimize the risks of congenital malformations and other complications.[91,93,97,98] Treatment of DKA does not differ from treatment given in the nonpregnant state except that fetal viability and well-being should be assessed.

The timing and mode of delivery depend on whether obstetric or maternal complications exist. In the absence of suspected problems, vaginal delivery at term is recommended. Elective delivery is indicated in the setting of poor metabolic control, significant diabetic complications, and fetal macrosomia with suspected birth weight greater than 4500 g.[92] Delivery is timed to avoid fetal growth into the macrosomic range while allowing sufficient fetal lung maturity. If corticosteroids are administered, close glucose monitoring is required because insulin requirements are likely to increase. Pregnancy progression beyond term is not recommended.

Gestational Diabetes

GDM is defined as glucose intolerance that begins (or is first detected) during pregnancy. As the incidences of both NIDDM and IDDM have increased, so has that of gestational disease.[103] It is important to detect and to address glycemic disorders because maternal glucose intolerance increases the likelihood of adverse perinatal outcomes, such as fetal macrosomia and maternal hypertensive disorders, even at glycemic levels that are considered below the threshold for diagnosis of diabetes.[104-107] GDM is also a risk factor for the subsequent development of nongestational diabetes; an increased risk is seen with obesity, higher HbA_{1c} values in pregnancy, advanced age at time of GDM diagnosis, lower beta cell function, and need for insulin dosing in late pregnancy.[108-111] It is recommended that all postpartum patients with GDM be educated about diet and exercise and undergo routine postnatal screening at repeated intervals long term.[108,109,112]

The exact protocol to follow for the diagnosis of GDM and preexisting, undiagnosed diabetes mellitus is controversial. It is recommended that pregnant patients undergo screening at

www.ketabpezeshki.com 66485457-66963820

the beginning of prenatal care in an effort to identify those patients who are at risk for GDM and pregestational diabetes mellitus to minimize adverse pregnancy outcome and progression of diabetic complications.[105] However, it remains unclear whether universal laboratory testing at the first prenatal visit (as opposed to clinical screening) is cost-effective or if this type of screening should be applied only to those populations with a high prevalence of diabetes.[105] The International Association of the Diabetes and Pregnancy Study Groups recommends laboratory screening of all women (if prevalence of disease is high in the population being tested) or only high-risk women at the first prenatal visit with subsequent testing at 24 to 28 weeks' gestation for all women unless they have already been diagnosed with a glycemic disorder.[105] The American Diabetes Association advocates selective laboratory assessment as soon as possible in gestation for patients at high risk for GDM. This group includes patients older than 25 years; certain high-risk ethnic groups; and patients with obesity, known first-degree relatives with diabetes, personal history of diabetes or glucose intolerance, and personal history of poor pregnancy outcome.[109] Average-risk women and those high-risk women not diagnosed with GDM early in pregnancy then undergo laboratory screening at 24 to 28 weeks' gestation.[111] On the other hand, the American College of Obstetricians and Gynecologists recommends universal laboratory screening.[108]

The majority of patients with GDM achieve metabolic control with dietary therapy. Traditionally, insulin administration is indicated if dietary control is unsuccessful[108,109] (see Table 179-1). Standard practice has been to avoid oral medications because of concerns for placental transfer. However, glyburide has minimal transfer, and studies comparing insulin with glyburide in GDM found that glyburide provided similar glycemic control without an increase in adverse pregnancy outcomes.[110,113,114] A summary from the Fifth International Workshop-Conference on GDM noted that glyburide may be considered in patients with GDM as long as care is taken to prevent maternal hypoglycemia.[115] Similarly, initial investigations of metformin in the setting of GDM have not noted any increase in perinatal complications, although some patients taking these agents have required supplemental insulin.[101,116] At this time, however, further study is recommended before its widespread use.[115] There are limited data for other oral medications.

Thyroid Disorders

The peak incidence of thyroid disease is in women of childbearing age. Both hypoactivity and hyperactivity lead to obstetric complications and warrant specific therapy. As with other organ systems, there are physiologic changes in thyroid function that occur in normal pregnancies. Human chorionic gonadotropin (hCG) is structurally similar to thyroid-stimulating hormone (TSH) and stimulates the thyroid gland. As a result, women with normal pregnancies may experience a temporary suppression in TSH production and slightly lower TSH levels during the first trimester, which mirrors the high circulating hCG levels seen at this gestational period. This hCG-mediated effect may lead to a transient hyperthyroidism if hormone levels are markedly increased. Estrogen also increases the amount of thyroid hormone–binding proteins, which ultimately leads to an increase in the amount of total T_4 and T_3 even though free hormone levels remain normal.

During the first trimester, the fetus is entirely dependent on placental transfer of maternal thyroid hormone. After 10 to 12 weeks of gestation, the fetus makes its own thyroid hormone but still requires placental transport of iodine and adequate maternal intake of this element (250 μg/day).

Hyperthyroidism

The most common cause of hyperthyroidism is Graves' disease, in which autoimmune thyroid-stimulating immunoglobulin results in increased production and release of thyroid hormone. Because the symptoms of hyperthyroidism resemble the physiologic changes expected during pregnancy in many respects, the diagnosis may not be immediately evident. Patients with Graves' disease have disease-specific findings including a diffusely enlarged, soft, mildly tender thyroid gland, exophthalmos, and dermopathy. Other symptoms, such as dyspnea, heat intolerance, hyperemesis, tachycardia, palpitations, systolic flow murmurs, increased appetite, and fatigue, are common to both conditions, making clinical diagnosis difficult. In cases of suspected hyperthyroidism, thyroid function studies and antibody assays are indicated and will confirm the presence of disease.

There are several obstetric concerns for both the mother and the fetus in the setting of untreated clinical hyperthyroidism (see Table 179-1).[117] Thyroid storm is the most serious manifestation of the disease. It may be precipitated by stressors such as infection and delivery, and it is manifested with fever, dysrhythmias, myocardial dysfunction, mental status changes, and circulatory collapse. In addition to the more general complications stemming from thyroid hormone excess, Graves' disease places the fetus at risk for autoimmune-mediated thyroid dysfunction through placental transfer of maternal thyroid-stimulating immunoglobulins. Up to 17% of neonates of mothers with Graves' disease and positive thyroid-stimulating immunoglobulin values have transient hyperthyroidism lasting 3 to 12 weeks. The condition gradually clears as maternal antibodies are metabolized.[118] Manifestations are potentially severe and include irritability, tachycardia, goiter, cardiomegaly, congestive heart failure, premature craniosynostosis, low birth weight, and failure to thrive.[119] These infants also have an increased mortality rate, so routine thyroid assessment is indicated in all infants born to mothers with autoimmune thyroid disease.[120]

The mainstay of treatment of hyperthyroidism (see Table 179-1) consists of antithyroid drugs. Propylthiouracil is preferred to methimazole because of an increased potential for adverse congenital drug effects from methimazole.[120,121] However, both medications cross the placenta and can stimulate the fetal thyroid, so maternal thyroid function should be assessed periodically during pregnancy with the goal of keeping free thyroxine in the high-normal range.[120] Most patients respond to pharmacologic manipulation, although thyroidectomy may be considered in severe cases in which patients cannot tolerate antithyroid medication or in the setting of medication failure.[120] Use of iodine-131 radionuclide to ablate the maternal thyroid is contraindicated because it will also destroy the fetal thyroid gland.

Additional therapy with beta-blockade to mitigate the hemodynamic effects of sympathetic stimulation may be required in certain cases pending adequate disease control with antithyroid medications. In the nonpregnant patient, iodides may be used to transiently block the release of stored T_4 from the thyroid gland and to inhibit organification of iodide. However, the fetal thyroid is extremely sensitive to iodide, which may result in neonatal goiter and hypothyroidism. Therefore, iodide is considered class D in pregnancy, and its use should be reserved for severe cases with duration of therapy limited to a period of days. As with other autoimmune conditions, transient improvement of Graves' disease during pregnancy is common, with rebound and clinical deterioration occurring in a majority of patients after delivery.[122]

Postpartum Thyroiditis

Postpartum thyroiditis is a relatively common condition that develops in approximately 4 to 8% of parturients within 9 months of delivery.[117,123,124] The risk for development of postpartum

www.ketabpezeshki.com 66485457-66963820

thyroiditis is increased in patients with diabetes as well as in patients who have thyroid peroxidase antibodies.[120] Patients experience transient hyperthyroidism, transient hypothyroidism, or transient hyperactivity followed by transient hypoactivity. Symptoms are typical for the type of impairment. The need for medication seems to be confined to those patients with postpartum hypothyroidism[123]; thyroid replacement is recommended for patients who are symptomatic or who have a markedly elevated TSH. Hypothyroid patients trying to conceive another pregnancy should be treated as well.[120] On occasion, patients with transient hyperthyroidism require a short course of beta-blockers, but antithyroid drugs are not helpful because the pathophysiologic process relates to release of preformed thyroid rather than to excess thyroid hormone production. Approximately 30% of patients with postpartum thyroiditis develop permanent thyroid failure, and this percentage is increased to 50% or more in patients with postpartum hypoactivity.[124,125]

Hypothyroidism

The most common cause of hypothyroidism is Hashimoto's thyroiditis. Overt hypothyroidism is often associated with infertility, so most cases seen during pregnancy are less severe or subclinical forms or occur in patients already undergoing levothyroxine therapy for known disease. Undiagnosed subclinical hypothyroidism may be manifested during pregnancy as physiologic adjustments result in a greater requirement for thyroid hormone production. In addition, iodine deficiency may be exacerbated by pregnancy because renal losses of iodine increase as the glomerular filtration rate increases and as the fetus diverts iodine for its own thyroid hormone synthesis. When signs and symptoms do occur, they are identical to those in the nonpregnant state. Myxedema coma is extremely rare but should be considered along with other causes of coma in a pregnant patient.

As with hyperthyroidism, there is an increased incidence of adverse maternal and fetal effects in women with clinical hypothyroidism (see Table 179-1).[117,126] The majority of patients who are already undergoing treatment for hypothyroidism will require an increased dosage of levothyroxine during pregnancy, and close monitoring of thyroid function is recommended as soon as possible after conception.[120,127,128] Treatment of newly diagnosed patients consists of prompt initiation of thyroid hormone replacement with the goal being to achieve a normal TSH level.[117,120]

Approximately 3 to 5% of women of childbearing age have subclinical hypothyroidism,[129] as defined by an elevated TSH level and a normal T_4 level.[130] It has been noted that clinical and subclinical hypothyroidism result in adverse perinatal outcomes and adverse neurologic outcomes for affected infants.[120,130] One study also found an increased risk of placental abruption and preterm delivery in subclinical hypothyroidism, and the authors suggested that premature birth may have a direct impact on cognitive outcome in affected infants.[131] Conversely, another more recent analysis found no increase in adverse outcomes in subclinical hypothyroidism.[132]

The issue of whether to provide routine prenatal screening for hypothyroidism remains controversial. At present, both the American College of Obstetricians and Gynecologists and the Endocrine Society note that there is insufficient evidence to confirm that diagnosis and treatment of subclinical disease significantly improve perinatal neurologic outcomes.[120,130] These organizations state that screening should include symptomatic patients and those at risk for disease (prior thyroid diagnoses or other endocrine or autoimmune problems).[120,130] On the other hand, other sources recommend assessment of TSH levels in all women before conception or as soon as possible after becoming pregnant because targeted screening may miss up to one third of affected women.[133,134]

Congenital hypothyroidism, associated with severe mental retardation, occurs in approximately 4 in 10,000 births in the United States.[135] It is most often the result of sporadic fetal thyroid dysgenesis or ectopy rather than maternal thyroid dysfunction.[136] Diagnosis is often difficult because clinical signs and symptoms may be masked by maternal thyroid hormone. Congenital hypothyroidism is successfully treated with hormone replacement begun in the first days of life, and screening for congenital hypothyroidism is routinely performed in most developed countries.

Systemic Infections

Tuberculosis

Acquisition and presentation of tuberculosis are unchanged during pregnancy. However, the effect of tuberculosis on pregnancy is unclear. Some studies reveal an increase in gestational complications[137-139] (see Table 179-1), but these outcomes are likely to be significantly influenced by the site of disease and specifics of treatment. In addition, conclusions are limited by the fact that these studies are often small or performed retrospectively. Other small studies found no significant increase in gestational complications in 32 and 111 pregnant patients with properly treated tuberculosis.[140,141] Complications are more likely in patients with inadequate or delayed treatment, delayed diagnosis, and extrapulmonary (extranodal) tuberculosis.[137,138] Neonatal tuberculosis acquired by exposure to undiagnosed and untreated active disease places infants at significant risk for acquiring tuberculosis during the first year of life, with significant mortality. In addition, congenital tuberculosis is possible after the fetus becomes infected through the placenta or aspiration of infected amniotic fluid. The latter is rare if the mother has received appropriate therapy.

Current recommendations are to administer a tuberculin skin test early in pregnancy to all patients at high risk for disease and to obtain a chest radiograph if the purified protein derivative (PPD) skin test response is positive or if the patient's signs and symptoms suggest tuberculosis. Universal screening should be considered in urban areas with a high prevalence of disease. Definitive treatment is indicated in all pregnant patients with confirmed tuberculosis as well as in those high-risk women with suspected disease (see Table 179-1).[142] Isoniazid, ethambutol, and rifampin in their usual doses have not been shown to be teratogenic to human fetuses and are acceptable during pregnancy and breastfeeding.[143] On the other hand, streptomycin causes fetal ototoxicity, and little is known about the safety of other second-line agents during pregnancy. These less commonly used agents should be avoided except in the case of multidrug-resistant disease (MDR-TB). One retrospective study of 38 gravidas with MDR-TB found no significant increase in perinatal complications, and even patients with drug-resistant disease can be considered for continuation of pregnancy.[144]

HIV Infection and AIDS

Human immunodeficiency virus (HIV) infection is one of the leading health problems in pregnancy. In 2008, 25% of reported cases of HIV infection and acquired immunodeficiency syndrome (AIDS) in the United States were in women, with a significant percentage being in women of childbearing age.[145] Estimates of the seroprevalence of HIV infection in pregnant women vary on a regional basis. In the United States, the overall prevalence and number of perinatally infected infants are low but also vary according to the population, with increased rates seen in the southern states and in the black and Hispanic populations.[145,146]

The mechanism of vertical transmission is multifactorial. The majority of cases are thought to occur during delivery through exposure to maternal blood and secretions; other infants are likely

www.ketabpezeshki.com 66485457-66963820

to be infected in utero or through breast-feeding. Various factors influence the rate of transmission. The most important is maternal viral load, although infection can occur even with low maternal viral load.[147-149] Other contributing factors for transmission include vaginal infections, injection drug use, premature delivery, low birth weight, and prolonged rupture of membranes.[147,149-151] Vertical transmission of HIV in the United States and other developed countries has declined significantly since its peak in the early 1990s because of the implementation of a number of interventions, including routine voluntary testing, antiretroviral therapy (ART), use of elective cesarean section, and avoidance of breast-feeding.[152] However, vertical transmission remains a concern in women without adequate prenatal care as well as a global concern. It is estimated that perinatal infection occurs in approximately 20% of deliveries if the mother is untreated, whereas the previously mentioned interventions reduce this rate to less than 1 or 2%.[149,150,152-154] Because of this beneficial effect, it is recommended that all pregnant women undergo screening during their routine prenatal evaluation, with repeated screening in the third trimester for women engaging in high-risk behavior or those who have concurrent sexually transmitted diseases (STDs). Rapid HIV screening is recommended for women in labor whose HIV status is unknown.[147,155,156]

Treatment of the pregnant patient with HIV infection includes appropriate ART as well as standard therapy for opportunistic infections (see Table 179-1).[147,157] There are limited data on specific therapy for opportunistic infections during pregnancy, but the practitioner should take into account the fact that medication clearance may be affected by various pregnancy-related changes, including increased renal clearance, dilutional anemia, and fetal metabolism of medications.[157] Periodic ultrasonographic assessments of fetal growth are indicated if required medications have an unknown safety profile in pregnancy.

Optimal therapy to prevent vertical transmission includes three stages: antepartum administration of highly active antiretroviral therapy (HAART), intrapartum intravenous zidovudine dosing, and treatment of the infant with 4 to 6 weeks of zidovudine.[147,158] The specific ART regimen to follow depends on a number of variables. In patients who are already taking ART with good disease control (viral load < 1000 copies/mL) at the time or pregnancy diagnosis, the current medication regimen should be continued with the exception of efavirenz, which should be discontinued.[147] Women who have never received ART are started on a standard multidrug HARRT regimen that avoids use of efavirenz in the first trimester. Delayed initiation of HAART until the second trimester may be considered in women if the only goal of therapy is to prevent mother-to-child transmission (maternal viral load < 1000 copies/mL).[147,158] In HIV-infected mothers without prenatal care, intrapartum ART followed by postexposure zidovudine treatment of the infant reduces the likelihood of infection but is less effective than the recommended three-stage regimen.[147] Elective cesarean section is recommended in mothers with a viral load greater than 1000 copies/mL.[147] It is reasonable to present cesarean delivery as an option for patients with lower viral loads, although the benefit for these lower risk mothers in uncertain,[147,159] and the risk of mother-to-child transmission by vaginal delivery is very low when mothers have received effective HAART.[148,160]

Whereas breast-feeding is associated with mother-to-child transmission of HIV infection and is not recommended in urban areas with access to formula preparations, it remains the preferred mode of feeding in resource-poor areas where formula use is not possible. Studies have shown that continued infant prophylaxis with ART is effective in reducing mother-to-child transmission through breast-feeding, with the absolute risk of transmission being very low.[161,162] Exclusive breast-feeding has also been shown to confer a mortality benefit and to reduce the risk of acquired infections,[163,164] and the World Health Organization now encourages exclusive breast-feeding in women when adequate and safe formula-feeding is not possible.[165] Ideally, breast-feeding mothers should be maintained with ART. If ART is not available, breast-feeding is preferable when replacement nutrition is not an option.[165]

Even in the setting of ART, commonly used serologic tests to detect antibodies for HIV yield positive results in virtually all neonates born to HIV-positive mothers because of placental transfer of maternal antibodies. These antibodies may be present for up to 18 months and are not necessarily indicative of infection. The preferred means of diagnosis of perinatal HIV infection is by use of assays to detect viral RNA or DNA. Infants are considered noninfected if there have been two negative viral assays after 1 month of age, with one of the assays being done after 4 months of age, or with negative results of two antibody tests done on separate occasions after 6 months of age. In addition, there should be no clinical or other laboratory findings to suggest infection.[166] Clinical assessment for possible HIV infection is also warranted. Infants with AIDS typically present with recurrent bacterial infections, *Pneumocystis* pneumonia, encephalopathy, extrapulmonary tuberculosis, and generalized wasting. Recent analysis reveals that HAART therapy in infants and children is extremely effective in reducing HIV-related morbidity and mortality.[167]

The effects of pregnancy in women with symptomatic HIV infection include an increased incidence of infant mortality, prematurity, stillbirth, and low birth weight and also gestational diabetes.[164,168,169] Seropositive mothers who undergo cesarean delivery generally have an uncomplicated postoperative course, although some studies note a slightly increased risk of postpartum endometritis and other maternal infections, with the highest rate of infection seen in women who have low $CD4^+$ cell counts.[170-172] It is also important to consider the effect of ART on pregnancy outcomes. It is recommended that efavirenz be avoided in the first trimester of pregnancy because of potential teratogenicity and fetal anomalies.[147,173-175] Overall, however, most antiretroviral medications are considered safe in this regard. Several large studies have noted no increase in adverse outcomes in women taking ART, with the possible exception of preterm delivery, although this remains a matter of controversy.[176-178]

The effect of pregnancy is unclear. An observational cohort study in which a majority of women were using HAART found that pregnancy had no impact on the rate of disease progression.[179] Additional studies are necessary for definitive conclusions to be drawn.

Syphilis

The incidence of primary and secondary syphilis among reproductive-age women in the United States increased during 2004 through 2008, with a current rate of 1.5 cases per 100,000 women.[180] Unfortunately, the incidence of congenital syphilis has shown a similar increase from 2005 to 2008, with a current rate of 8.2 per 100,000 live births.[181] Of all the congenital syphilis cases for 2008, half were born to black mothers and an additional 30% to Hispanic mothers, highlighting the need for better screening in these high-risk populations.[181]

Syphilis causes numerous gestational complications (see Table 179-1), but its most significant sequela is congenital syphilis. This syndrome is characterized by clinical abnormalities such as hepatosplenomegaly, osteochondritis, jaundice, rash, lymphadenopathy, rhinitis, Hutchinson's teeth, and anemia. Infant mortality for cases occurring in 2008 was 6.5%.[181] Screening for all pregnant patients is indicated at the first prenatal visit and again in the early third trimester and at delivery for high-risk patients[156] because vertical transmission rates can be reduced significantly with appropriate penicillin therapy.[156,182] Either the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) test

www.ketabpezeshki.com 66485457-66963820

can be used to detect nontreponemal antibody. Pregnancy may cause false-positive results for nontreponemal studies, so confirmation with specific treponemal tests is indicated for a positive VDRL or RPR study. Patients with latent syphilis and those whose titers fail to respond to therapy should undergo cerebrospinal fluid analysis to screen for tertiary syphilis. In addition, fetal ultrasonography before the 20th week of gestation is indicated to assess for abnormalities consistent with congenital syphilis.[156]

Treatment is identical to that given to nonpregnant patients with use of benzathine penicillin G appropriate for the disease stage[156] (see Table 179-1). Penicillin-allergic patients are sometimes treated with macrolides.[182] However, it is preferable that these patients undergo skin testing and desensitization if the skin test result is positive because alternative therapy is not reliably effective in preventing congenital syphilis.[156,183,184] Treatment failures are rare with appropriately administered penicillin but do occur. Failures leading to congenital syphilis are more likely in mothers with secondary syphilis, high VDRL or RPR levels, and an interval from treatment to delivery of less than 30 days.[156,182,184,185]

Hepatitis

Hepatitis B

The prevalence of hepatitis B virus (HBV) infection among pregnant women varies by the population studied, with the highest rates seen in Asians and women of African descent.[186,187] The rate of vertical transmission depends on the acuity of maternal infection and when it occurs during the gestation. Perinatal transmission is approximately 10 to 20% in women seropositive for HBsAg alone but approaches 90% in mothers who are seropositive for HBsAg and HBeAg, and it is also more likely if the mother has acute infection during the third trimester.[188] Of infants who have HBV infection, up to 90% become chronic carriers as adults and are at risk for complications such as cirrhosis and hepatocellular carcinoma.[188]

Routine screening for HBV during early pregnancy is recommended because treatment with hepatitis B immune globulin and hepatitis B vaccine is effective in reducing the rate of vertical transmission.[156,188-190] Repeated testing is indicated at the time of delivery for women at high risk for infection.[156] Although these therapies are effective in reducing neonatal infection, treatment failures do occur in the setting of maternal seropositivity for HBeAg and high viral loads of HBV DNA.[191,192] Studies suggest that lamivudine given in late pregnancy to these high-risk gravidas reduces viral transmission when it is given in conjunction with HBV vaccine and immune globulin.[193,194] Vaccination against HBV is currently recommended for all infants in the United States. The treatment schedule and the need for additional therapy with immune globulin vary according to maternal seropositivity. Infants of HBsAg-positive mothers should receive hepatitis B immune globulin and the first dose of vaccine within 12 hours of birth. Two additional doses of vaccine are administered at a later date.[188,195] Pregnancy is not a contraindication to either therapy. All HBsAg-negative gravidas at risk for HBV infection or other STDs or who are seeking STD treatment should receive the vaccine.[156] Pregnant patients who are exposed to HBV should receive both hepatitis B immune globulin and vaccine.

Hepatitis C

As with HBV, the prevalence of hepatitis C virus (HCV) infection among pregnant women varies by the population, ranging from less than 1% to approximately 4%. Vertical transmission is rare in mothers with anti-HCV antibodies and no circulating HCV RNA. However, perinatal transmission is significantly increased by the presence of HCV viremia, occurring in approximately 4 to 6% of cases.[196] The transmission rate is even higher in the setting of coinfection with HIV.[197,198] Unfortunately, cesarean delivery has not been shown to prevent HCV transmission.[156,188,197] No available vaccine or immune globulin exists to prevent hepatitis C, and routine prenatal screening is not indicated.[156]

Inflammatory Disorders

Rheumatic diseases or collagen vascular diseases are characterized by sterile inflammation in multiple anatomic sites. The most common rheumatic diseases encountered in pregnancy are systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). Gravid patients with collagen vascular disease may have preexisting cardiovascular or renal compromise and may not tolerate the increased intravascular volume and other physiologic changes that occur during pregnancy. The following discussion focuses on SLE, which is the rheumatic disease responsible for the majority of gestational complications. Most of the treatment guidelines for SLE are relevant to other rheumatologic disorders as well.

Systemic Lupus Erythematosus

SLE primarily affects women of reproductive age, and fertility is usually unaffected. The disease course during pregnancy varies, but studies indicate that acute flares occur in less than one third of patients in clinical remission at the time of conception.[199-201] Disease activity tends to involve the skin and musculoskeletal system, although renal involvement is not uncommon, especially in those patients with active lupus nephritis.[202-204] The gestational effects of SLE also depend on the underlying severity of disease. Patients with active disease, especially lupus nephritis, have a higher incidence of disease flares and pregnancy complications,[199,201,203-205] and it is best for women to achieve good disease control before pregnancy. Many patients have acceptable outcomes, but lupus pregnancies are associated with an increased maternal mortality as well as an increased rate of other complications, including preeclampsia, preterm delivery, thrombocytopenia, anemia, intrauterine growth retardation, fetal loss, and need for cesarean section.[199,205-207] Other comorbid conditions that adversely affect pregnancy, such as diabetes and thrombophilia, are also seen more commonly in SLE patients.[207] The risk of preeclampsia is especially increased in patients with active lupus nephritis.[201,203] As with other renal disease, increasing proteinuria warrants a careful evaluation to distinguish between lupus glomerulonephritis and preeclampsia. The presence of abnormal urine sediment, increasing titers of anti-DNA antibody, and decreasing levels of C3 and C4 suggest lupus nephritis.

Numerous other organ systems in addition to the kidneys are involved in SLE, and differentiation from pregnancy-related changes may be difficult. Mild thrombocytopenia occurs in normal pregnancies and is also common in patients with SLE, although the severity and clinical significance vary from patient to patient. Anemia is a frequent complication of lupus and magnifies the normal dilutional anemia of pregnancy. Various musculoskeletal and cutaneous symptoms associated with pregnancy, such as arthralgias and facial and palmar erythema, can also resemble active SLE. In addition, preexisting lupus rashes become more erythematous because of the increased cutaneous blood flow during pregnancy. Neurologic disease in SLE may be manifested as psychosis, seizures, chorea, or peripheral neuropathy. The incidence of these complications is low during pregnancy, although the occurrence of seizures in late pregnancy in patients with coexistent hypertension and renal insufficiency may pose a diagnostic dilemma between the neurologic effects of SLE and eclampsia.

www.ketabpezeshki.com 66485457-66963820

Other Rheumatologic Diseases

RA is characterized by chronic, destructive, symmetrical joint inflammation. Less common manifestations include the development of subcutaneous nodules, neuropathy, pleuropericarditis, and vasculitis. Systemic symptoms, including weight loss, lymphadenopathy, and fatigue, are common. Because the median age at onset is later with RA, this disorder is seen less frequently than SLE in the pregnant population.[208] Disease improvement has classically been estimated to occur in approximately two thirds of patients with RA. However, a prospective study noted disease improvement in about half of pregnant patients, with almost 40% of patients experiencing a subsequent exacerbation after delivery.[209]

Patients with RA tend to have good pregnancy outcomes in the setting of well-controlled disease. Those women with active disease are more likely to have small-for-gestational-age infants,[210] possibly as a result of underlying vasculopathy and associated effects on the placenta.[210]

Treatment

The rheumatologic diseases are similar with respect to the therapeutic approach. Corticosteroids form the basis of treatment for most disease complications and exacerbations. These drugs may result in a minimally increased risk of cleft deformities (data are inconclusive) but have not been found to have any other significant teratogenic effects and are considered relatively safe to use for disease control in pregnant patients.[211,212] Steroid use during pregnancy does have a dose-related effect on intrauterine growth retardation and predisposes the patient to GDM and hypertension, so close monitoring is advised.

Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are also a mainstay of therapy in many patients with rheumatic diseases and may be used in pregnancy. There are potential adverse effects of aspirin and NSAIDs on gestation, including miscarriage when they are taken early in pregnancy, premature closure of the fetal ductus arteriosus, increased maternal hemorrhage, and prolongation of gestation and labor when they are taken later in pregnancy. There are also conflicting data about an increased risk for gastroschisis, cleft defects, and cardiac defects with NSAID use.[213-217] If a true association exists, the risk for these anomalies remains extremely small in absolute terms. Use of these agents after 32 weeks of gestation should be avoided to minimize the risks of maternal and fetal hemorrhage and premature ductus closure.

Acute flares often require institution of cytotoxic drugs. Cyclophosphamide and methotrexate are contraindicated during the first trimester and should be used only in extreme circumstances because of their teratogenicity and abortifacient properties. Azathioprine has a much more favorable safety profile, and it is the cytotoxic agent of choice during pregnancy. Although the drug and its metabolites cross the placenta, it does not appear to have any major teratogenic effects.[218,219] There is an association between azathioprine use and preterm delivery and low birth weight, but it is likely that these adverse outcomes are also related to the underlying disease.[219,220] Cyclosporine also seems to lack teratogenicity and is an acceptable alternative to azathioprine.[221]

The antimalarial agents chloroquine and hydroxychloroquine are also useful in the treatment of SLE and RA and have been found to be safe during pregnancy. Gravis patients using antimalarials have a decrease in lupus activity, and as a result, these agents may allow a decrease in corticosteroid dosage.[222,223] In addition, patients who have been maintained with hydroxychloroquine before conception experience an increased rate of disease flares when the agent is discontinued.[222]

There are limited numbers of pregnant patients using the newer anti–tumor necrosis factor medications, such as infliximab and etanercept. A review of the Food and Drug Association database noted an increase in congenital malformations with anti–tumor necrosis factor agents.[224] However, other data suggest that these agents have an acceptable risk profile and that they may be continued in pregnancy.[225,226] Because the safety of these medications remains uncertain, their use should be reserved for patients with severe disease who are not adequately treated by other more established medications.[225]

KEY CONCEPTS

- The physiologic demands of pregnancy may cause previously occult medical conditions to become apparent and known problems to rapidly deteriorate.
- The physiologic adjustments of pregnancy alter the normal ranges for certain laboratory values. The adjusted values need to be considered in interpretation of results.
- The possibility of pregnancy should be considered in the differential diagnosis of certain conditions, including new-onset seizures or status epilepticus (eclampsia), glucose intolerance (GDM), persistent vomiting (hyperemesis gravidarum), and thyroid disorders.
- The immunosuppressive effects of pregnancy may cause temporary improvement in inflammatory and autoimmune conditions. This beneficial effect is lost in the postpartum period, resulting in exacerbations of asthma, thyroid disorders, and myasthenia gravis. Medication requirements can change drastically during pregnancy and the postpartum period.
- Certain medical conditions in the mother result in neonatal complications requiring special resuscitative measures.

Chapter 180

Drug Therapy in Pregnancy

Rania Habal

PERSPECTIVE

Major birth defects affect 3 to 5% of all live births.[1] Most are of unknown etiology, but 1 to 3% of these are thought to be due to pharmaceutical or environmental agents.[1,2] A *teratogen* is any chemical, pharmacologic, environmental, or mechanical agent that can cause deviant or disruptive development of the conceptus.[1,2] Included in this definition are functional impairment, growth restriction, and congenital malformations.[2] These may range from subtle neurobehavioral effects to devastating physiologic effects and physical deformities, including fetal death.[1-3] Why one pregnancy would be affected and not another remains to be elucidated. Highly teratogenic medications seem to be few in number, estimated at well below 50 agents (Box 180-1).[3,4]

The process of establishing teratogenicity is tedious and often flawed. Animal research, although valuable in determining risk initially, is not always applicable to humans,[1,2,5] and controlled prospective human studies are generally not performed for ethical reasons. As a result, much of our current knowledge on teratogenicity has been derived from case reports, case-control studies, or cohort studies, which are inherently weak in establishing a causal relationship.[1,2,5,6] These reports are often complicated by a multitude of confounding factors, making the determination of a causal link between a specific exposure and malformations difficult. The genetic background of the fetus, timing and duration of the exposure, environmental factors, multiple exposures, nutritional deficits, maternal illness, and illicit drug use all contribute to the outcome of pregnancy.[1,2,5,6] Large population studies are needed to understand the connection between the outcome of a pregnancy and an associated in utero exposure.[6] Finally, as in the case of diethylstilbestrol, teratogenicity may not be apparent for years after birth.

Classification of Teratogenic Risk

To aid physicians in determining the teratogenic potential of a particular medication, the U.S. Food and Drug Administration (FDA) assigns one of five letters, A, B, C, D, and X, to the drug, depending on the strength of evidence for its safety or teratogenicity (Box 180-2). This classification system has been criticized as overly simplistic and perhaps inaccurate.[1,2,5-7] Many clinicians believe that the classification system conveys the incorrect impression that there is a gradation of reproductive risk from exposure across categories (i.e., that risk increases from A to B to C to D to X) and that the drugs within a given category present similar reproductive risks.[7] Yet more than 90% of newly introduced drugs in the United States are assigned to class C, an undetermined teratogenic risk.[8] The FDA has acknowledged these problems, and in 2008 it proposed new rules for drug labeling during pregnancy. The proposed rules recommend giving a narrative description of the risks and the likelihood of developmental abnormalities and are awaiting the final stages of clearance.[9] Currently, a number of clinical teratology resources that assign risk are available online. These include TERIS, REPROTOX, and Micromedex REPRORISK (Shepard's *Catalog of Teratogenic Agents*).

PRINCIPLES OF DISEASE

Drugs may affect the fetus through a variety of mechanisms. Some alter the availability of substrates, such as vitamins, glucose, oxygen, and amino acids, needed for normal nutrition and growth.[1-3] Others directly affect cellular growth and differentiation. The age at which fetal exposure occurs is crucial in determining its impact on the pregnancy. The fetus is most vulnerable to toxic insults during the time of organogenesis (days 21-56 of fetal life).[1-3] Exposure during this period may result in major anatomic defects. Exposure after the period of organogenesis may affect the growth and development of the fetus.[1-3] Functional development of the central nervous system (CNS) is affected when it is exposed to a CNS teratogen during the 10th to 17th weeks of pregnancy.[1-3]

Drug Transfer across the Placenta

Drug transfer across the placenta occurs most commonly by simple passive diffusion or by protein transport.[1-3,10] A thin layer of trophoblastic cells is all that separates maternal from fetal circulation.[1-3,10] The degree to which a drug gains access to fetal circulation depends on molecular size, ionic state, lipid solubility, and extent of protein binding. Drugs with a molecular mass of less than 5 kDa readily diffuse.[1-3,10] Anionic forms diffuse through the lipid layer more readily than ionized forms.[1-3,10] Free drug diffuses more readily than a drug that is bound to plasma proteins.[1-3,10] Because fetal pH is slightly more alkalotic than maternal pH, weak organic acids (e.g., salicylate) may become ion trapped in the fetal circulation, increasing fetal exposure.[1-3,10]

Drug Transfer during Lactation

For the most part, drugs and substances that are ingested or injected by the mother diffuse passively into milk and then back into the maternal circulation for excretion.[11] The amount of drug diffusing into milk depends on many factors. Lipid-soluble and nonionic substances diffuse more readily, and highly protein bound substances diffuse less readily.[11] Whether a substance is concentrated in maternal milk or not, the neonate generally is able to detoxify it with no adverse effects, and only a few drugs pose a serious danger to a breast-feeding infant.[11-13] The interruption of

*Teratogen.

Box 180-2 Food and Drug Administration Classification: Teratogenic Risk of Drugs

- Class A: Controlled studies have shown no risk. Adequate well-controlled studies in pregnant women have failed to show risk to fetus.
- Class B: No evidence exists of risk for humans. Animal studies show risk or are negative, but no human studies have been done.
- Class C: Use may engender risk for fetus. Human studies are lacking, and animal studies may be positive or lacking. Potential for benefit may outweigh potential for harm.
- Class D: Positive evidence of risk is based on studies or postmarketing data. Potential for benefit may outweigh potential for harm.
- Class X: Drugs are contraindicated in pregnancy on the basis of human or animal studies or postmarketing reports that indicate benefit is clearly outweighed by risk.

breast-feeding should not be advocated except in rare situations of known drug toxicity to the infant and in all cases of maternal critical illness.[11,12] Table 180-1 summarizes the compatibility of medications and their effects in pregnancy and lactation.

DRUG THERAPY DURING PREGNANCY

In general, the health of the fetus is directly related to the health of the mother. Physicians should not withhold lifesaving medications from pregnant patients because of a reported risk to the fetus and should resuscitate pregnant patients according to advanced life support guidelines. Physicians may also prescribe any agent that presents maternal benefits outweighing the risks to the fetus. Included in this category are therapeutic medications for asthma, arrhythmias, status epilepticus, life-threatening overdoses, and human immunodeficiency virus (HIV) infection. When prescribing drugs to pregnant and lactating women, physicians must weigh the benefits of treatment against the inherent risks of treatment or disease, consider the pharmacokinetics of the drug during pregnancy and lactation, choose the drug with the lowest known toxicity, and use the lowest effective dose.

Analgesic Agents

Acetaminophen

Acetaminophen (paracetamol) is widely used during pregnancy and has not been associated with congenital malformations.[13-15] In fact, in a population-based case-control study, acetaminophen was associated with a decreased risk of certain craniofacial malformations when it was used for febrile illnesses in the first trimester.[13,15] Acetaminophen is safe during lactation because only a small amount is excreted into breast milk, and the amount involved is tolerated by the neonate's sulfhydration pathway.[11-13] However, in overdose situations, there may be an increase in the incidence of spontaneous abortion and fetal demise, especially when antidote treatment with *N*-acetylcysteine is delayed.[13,16]

Aspirin

Early studies linked aspirin to an increased risk of perinatal and neonatal bleeding, increased risk of postmaturity, prolonged labor, low birth weight, neonatal hypoglycemia, neonatal metabolic acidosis, and neonatal death.[13,14] However, a number of meta-analyses in humans failed to demonstrate a teratogenic effect of aspirin,[13,14,17,18] and in the Perinatal Antiplatelet Review of International Studies (PARIS) Collaboration, low doses of aspirin were actually found to be beneficial and to reduce the risk of preeclampsia, premature birth, and adverse perinatal outcomes.[19] There was a trend, however, toward a slightly increased incidence of gastroschisis (a defect in the abdominal wall through which abdominal contents protrude) with use of nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin in the first trimester.[13,18-20] Aspirin is excreted into breast milk, and because of its association with Reye's syndrome, its use is therefore discouraged in breast-feeding.[11-13]

Nonsteroidal Anti-Inflammatory Drugs

Prostaglandin synthesis inhibitors such as NSAIDs have been shown to block blastocyst implantation and may therefore inhibit conception.[20] Their use in the first trimester has been linked to an increased risk of spontaneous abortions and a slight increase in cardiac septal defects, oral clefts, and gastroschisis.[13,14,20-22] When they are used in the third trimester, NSAIDs inhibit labor and have been used as tocolytic agents for premature labor.[13,14,21] When they are used in the latter part of pregnancy, NSAIDs have been linked to a number of negative effects on the neonate, most notably premature closure of the ductus arteriosus, leading to neonatal pulmonary hypertension and death.[13,14,21,23] An increased incidence of fetal periventricular hemorrhages, fetal nephrotoxicity, oligohydramnios, and neonatal gastrointestinal hemorrhage has also been reported.[13,14,21,23] Their use in the latter part of pregnancy is therefore discouraged. NSAIDs in general appear to be safe during lactation.[12,13]

Opiate Analgesics

In general, short-term, episodic use of opiates such as oxycodone, hydrocodone, morphine, and fentanyl appears to be safe in pregnancy.[13,14] Their use near term, however, may result in severe respiratory depression of the neonate.[13,14] In addition, prescribing of narcotics for long periods can lead to fetal addiction, low birth

Table 180-1 Summary of Medication Safety in Pregnancy and Lactation

MEDICATION	PREGNANCY	LACTATION
Analgesic Agents		
Acetaminophen or paracetamol	Safe (B)	Compatible
Nonaspirin nonsteroidal anti-inflammatory drugs (NSAIDs)	Discouraged (D) in third trimester because of premature closure of ductus arteriosus	Compatible
Salicylate	Traditionally discouraged (D); may be safe in low doses	Discouraged because of risk of Reye's syndrome
Opiates: Most opiates are considered safe for short-term use, but all are reclassified in category D if they are used for prolonged periods or if they are used in high doses at term (because of respiratory depression in the newborn). Do not use opiates combined with aspirin or NSAIDs. Use of opiates during breast-feeding may result in sedation and respiratory depression of the newborn, especially if high doses are used for prolonged periods. These infants may require close observation		
Codeine	Safe (C) for short-term use, but not at term (D)	Discouraged if longer than 2 days
Fentanyl	Safe (C) for short-term use, but not at term (D)	Compatible
Hydrocodone	Safe (C) for short-term use, but not at term (D)	Probably compatible
Hydromorphone	Safe (C) for short-term use, but not at term (D)	Probably compatible
Meperidine	Safe (C) for short-term use, but not at term (D)	Discouraged
Methadone	Safe (C) for short-term use, but not at term (D)	Compatible
Morphine	Safe (C) for short-term use, but not at term (D)	Compatible
Oxycodone	Safe (C) for short-term use, but not at term (D)	Probably compatible
Anesthetics, Sedative-Hypnotics, and Neuromuscular Blockers		
Etomidate	Safety unknown (C)	Insufficient data; probably compatible after 12 hours
Ketamine	Probably safe (B); risk with high doses close to delivery	Insufficient data; probably compatible after 12 hours
Lorazepam	Probably safe for short periods; unsafe for chronic use (D)	Insufficient data; potential toxicity
Midazolam	Probably safe for short periods; unsafe for chronic use (D)	Insufficient data; potential toxicity
Propofol	Insufficient data; potential neonatal depression (B)	Insufficient data; probably compatible after 12 hours
Neuromuscular blockers: Breast-feeding is not appropriate in critically ill, paralyzed patients.		
Rocuronium	Potential risk around delivery (C)	Safety unknown
Succinylcholine	Potential risk around delivery (C)	Safety unknown
Vecuronium	Potential risk around delivery (C)	Safety unknown
Anticoagulants and Thrombolytics		
Heparin	Safe (B)	Compatible
Low-molecular-weight heparin	Safe (B)	Compatible
Warfarin	Contraindicated (X)	Compatible
Thrombolytics: Potential benefits of drug treatment outweigh potential risks to pregnancy outcome. Breast-feeding is not appropriate in the critically ill.		
Alteplase	Safety unknown (C)	Safety unknown
Reteplase	Safety unknown (C)	Safety unknown
Streptokinase	Safety unknown (C)	Safety unknown
Tenecteplase	Safety unknown (C)	Safety unknown
Urokinase	Safety unknown (C)	Safety unknown
Antidotes: Potential benefits of drug treatment outweigh potential risks to pregnancy outcome. Breast-feeding is not appropriate in the critically ill and the poisoned patient.		
Deferoxamine antidote: iron toxicity	Safety unknown (C)	No data; probably compatible
Digoxin immune Fab antidote: digitalis	Safety unknown (C)	No data; probably compatible
Dimercaprol antidote: heavy metals	Safety unknown (C); teratogenic in animals	No data; probably compatible
Flumazenil antidote: benzodiazepines	Safety unknown (C); safe in animals	No data; probably compatible
Fomepizole antidote: toxic alcohols	Safety unknown (C)	Safety unknown
Hydroxycobalamin antidote: cyanide	Safe (B)	Compatible
Methylene blue antidote: methemoglobinemia	Known human risk (C)	Discouraged
N-Acetylcysteine antidote: acetaminophen overdose	Safe (B)	Compatible
Naloxone antidote: narcotics	Safety unknown (C); may precipitate fetal withdrawal	Safety unknown
Physostigmine antidote: anticholinergics	Safety unknown (C)	Safety unknown

www.ketabpezeshki.com 66485457-66963820

Table 180-1 Summary of Medication Safety in Pregnancy and Lactation—cont'd

MEDICATION	PREGNANCY	LACTATION
Pralidoxime antidote: organophosphates	Safety unknown (C)	Safety unknown
Pyridoxine antidote: isoniazid overdose	Safe (B)	Compatible
Succimer antidote: lead poisoning	Safety unknown (C); teratogenic in animals	Safety unknown
Antimicrobials: Use of antibiotics near term may interfere with culture results in neonates.		
Aminoglycosides	Discouraged (D)	Compatible
Cephalosporins		
First generation: cephalexin, cefazolin, cefadroxil	Safe (B)	Compatible
Second generation: cefuroxime, cefaclor, cefoxitin, cefprozil	Safe (B)	Compatible
Third generation: cefdinir, cefotaxime, ceftazidime, ceftriaxone, cefpodoxime, ceftizoxime	Safe (B)	Probably compatible
Chloramphenicol	Probably safe until term (C); contraindicated at term (gray baby syndrome)	Discouraged (gray baby syndrome)
Clindamycin	Relatively safe (B)	Compatible, but caution advised (diarrhea and bloody stools in nursing infant)
Linezolid	Safety unknown (C) Known animal risk	Safety unknown
Macrolides		
Azithromycin	Safe (B)	Compatible
Clarithromycin	Probably safe (C); evidence is inconclusive	Probably compatible; evidence is inconclusive
Erythromycin: Do not use estolate salt.	Safe (B)	Compatible
Metronidazole	Contraindicated in first trimester, safe in second and third trimesters (B)	Discouraged
Nitrofurantoin	Safe (B), except in third trimester (hemolytic anemia in newborn)	Probably compatible
Penicillins		
First generation: penicillin G, benzathine penicillin, Bicillin, penicillin VK	Safe (B)	Compatible
Second generation: oxacillin, dicloxacillin, nafcillin	Safe (B)	Compatible
Third generation: ampicillin, ampicillin-sulbactam, amoxicillin, amoxicillin-clavulanate	Safe (B)	Compatible
Fourth generation: ticarcillin, ticarcillin-clavulanate, piperacillin, piperacillin-tazobactam, carbenicillin	Safe (B)	Probably compatible
Quinolones have been linked to abnormalities in cartilage and bone, but recent data are contradictory. Their use is discouraged during pregnancy and lactation.		
First generation: nalidixic acid	Use is discouraged (C)	Use is discouraged
Second generation:		
ciprofloxacin	Use is discouraged (C)	Compatible
norfloxacin, ofloxacin	Use is discouraged (C)	Safety unknown
Third generation: levofloxacin	Use is discouraged (C)	Safety unknown
Fourth generation: gatifloxacin, moxifloxacin	Use is discouraged (C)	Safety unknown
Sulfonamides	Use is discouraged near term (C) (kernicterus in newborn); contraindicated throughout pregnancy if combined with trimethoprim	Probably compatible, except in premature infants or infants with G6PD deficiency or hyperbilirubinemia
Tetracyclines have been linked to abnormalities in teeth and bone; their use in pregnancy is discouraged.		
Tetracycline	Contraindicated (D)	Compatible
Doxycycline	Contraindicated (D)	Discouraged
Vancomycin	Probably safe (C); insufficient data	Safety unknown
Antifungals		
Clotrimazole	Relatively safe (C)	Safety unknown
Fluconazole	Contraindicated (D)	Probably compatible
Ketoconazole	Insufficient data (C)	Safety unknown
Nystatin	Relatively safe (C)	Safety unknown
Terbinafine	Probably safe (B)	Safety unknown
Antituberculous medications in general present a maternal benefit that is much greater than the fetal or embryonic risk and may be prescribed during any stage of pregnancy when indicated.		
Isoniazid	Relatively safe (C)	Probably compatible
Rifampin	Relatively safe (C)	Probably compatible
Ethambutol	Relatively safe (C)	Probably compatible

Table 180-1 Summary of Medication Safety in Pregnancy and Lactation—cont'd

MEDICATION	PREGNANCY	LACTATION
Antiviral Agents		
Antiherpetic medications		
Acyclovir	Relatively safe (B)	Compatible
Famciclovir	Safety unknown (B)	Discouraged
Valacyclovir	Relatively safe (B)	Compatible
Anti-influenza agents: Potential benefits of drug treatment may outweigh potential risks to pregnancy outcome.		
Amantadine	Possible risk (C)	Safety unknown
Oseltamivir	Insufficient data; minor risks in rats (C)	Safety unknown
Neurologic Medications		
Anticonvulsants: Use of highly teratogenic anticonvulsants is contraindicated unless convulsions are refractory. Monotherapy is recommended. Newer anticonvulsants appear to be safer, although data and experience remain limited.		
Carbamazepine	Known teratogen (D)	Probably compatible
Lamotrigine	Safety unknown (C)	Safety unknown
Levetiracetam	Data limited (C)	Safety unknown
Phenobarbital	Discouraged (D)	Discouraged
Phenytoin	Known teratogen (D)	Compatible
Topiramate	Data limited (C)	Safety unknown
Valproic acid	Known teratogen (D)	Probably compatible
Cardiac Medications		
Antiarrhythmics: In cases of refractory arrhythmias, the benefits to the mother may outweigh risks to the fetus or embryo. Critically ill patients are not expected to breast-feed.		
Adenosine	Safe (C)	Compatible
Amiodarone	Discouraged (D)	Discouraged
Digoxin	Safe (C); caution in third trimester (oxytocic)	Compatible
Flecainide	Safety unknown (C)	Probably compatible
Ibutilide	Safety unknown (C); teratogenic in animals	Discouraged
Lidocaine	Safe (B)	Probably compatible
Procainamide	Not teratogenic, but associated with lupus-like reaction (C)	Compatible
Quinidine	Safe (C)	Compatible
Sotalol	Probably safe (B)	Probably compatible
Antihypertensives: Angiotensin antagonists and angiotensin-converting enzyme inhibitors have been associated with fetal renal agenesis, oligohydramnios, and stillbirths. They are contraindicated in pregnancy.		
Angiotensin-converting enzyme inhibitors	Discouraged (D)	Variable safety
Angiotensin II receptor antagonists	Discouraged (D)	Safety unknown
Beta-blockers: Beta-blockers have been associated with growth restriction and small-for-gestational-age babies. Caution is advised when they are prescribed in the first trimester or for prolonged periods. At term, some have been associated with neonatal bradycardia, hypoglycemia, and respiratory depression.		
Atenolol	Caution is advised (D)	Potential toxicity
Esmolol	Caution is advised (C)	Safety unknown
Labetalol	Probably safe (C)	Probably compatible
Metoprolol	Caution is advised (D)	Potential toxicity
Propranolol	Caution is advised (C)	Probably compatible
Calcium channel blockers: Data are conflicting. Teratogenic effects in animals have not been found in humans. Evidence remains insufficient, but observational studies are leaning toward their safety in pregnancy.		
Amlodipine	Safety unknown (C)	Safety unknown
Diltiazem	Insufficient evidence (C) but has been used safely	Probably compatible
Nicardipine	Caution is advised (C)	Safety unknown
Nifedipine	Insufficient evidence (C) but has been used safely; sublingual form is contraindicated	Probably compatible
Verapamil	Insufficient evidence (C) but has been used safely	Probably compatible
Diuretics: Caution for dehydration and electrolyte abnormalities.		
Furosemide	Caution is advised (C)	Caution is advised
Hydrochlorothiazide	Caution is advised (C); contraindicated in gestational hypertension	Caution is advised
Nitrates		
Nitroglycerin	Probably safe (C)	Probably compatible
Nitroprusside	Caution is advised (C)	Potential toxicity
Others		
Clonidine	Caution is advised (C)	Safety unknown
Hydralazine	Safe (C)	Compatible
Methyldopa	Safe (B)	Compatible

www.ketabpezeshki.com 66485457-66963820

Table 180-1 Summary of Medication Safety in Pregnancy and Lactation—cont'd

MEDICATION	PREGNANCY	LACTATION
Endocrine Medications		
Medications used in the treatment of diabetes		
Insulin	Safe (B)	Compatible
Sulfonylurea: Data on sulfonylureas in pregnancy are limited. They are considered acceptable alternatives to insulin in areas where insulin use is not feasible. Hypoglycemia may occur in nursing infants. Nursing infants should be monitored		
Glipizide	Insufficient evidence (C); fetotoxicity in animals	Caution is advised
Glyburide	Insufficient evidence (C)	Caution is advised
Metformin	Insufficient evidence (C)	Caution is advised
Thyroid medications		
Levothyroxine	Safe (B)	Compatible
Propylthiouracil	Insufficient data (D)	Compatible
Methimazole	Discouraged; fetotoxicity reported	Compatible
Gastrointestinal Medications		
Antacids		
H_2 blockers		
Famotidine	Low risk (B)	Probably compatible
Ranitidine	Safe (B)	Probably compatible
Nizatidine	Low risk (B)	Probably compatible
Cimetidine	Safe (B)	Compatible
Proton pump inhibitors		
Omeprazole	Low risk (C)	Safety unknown
Esomeprazole	Low risk (B)	Safety unknown
Lansoprazole	Low risk (B)	Safety unknown
Pantoprazole	Low risk (B)	Safety unknown
Antiemetics		
Dopamine antagonists		
Metoclopramide	Safe (B)	Potential toxicity
Prochlorperazine	Safe (C)	Potential toxicity
Promethazine	Safe (C)	Discouraged
5-HT_3 antagonists: generally safe		
Dolasetron	Low risk (B)	Probably compatible
Granisetron	Low risk (B)	Probably compatible
Ondansetron	Safe (B)	Probably compatible
Respiratory Medications		
Medications used in the treatment of asthma, allergies, and upper respiratory infection: For asthmatic patients, maternal benefits outweigh risks to fetus or embryo.		
Anticholinergic agents		
Ipratropium	Safe (B)	Safety unknown
Beta-adrenergics considered safe for short-term use		
Albuterol	Safe (C)	Probably compatible
Epinephrine	Potential risk (C)	Potential toxicity
Terbutaline	Potential risk (B); recent label change by FDA	Probably compatible
Corticosteroids safe for short-term use: Human data suggest an increased risk of orofacial clefts.		
Methylprednisolone	Safe for short-term use (C)	Compatible
Prednisolone	Safe for short-term use (C)	Compatible
Prednisone	Safe for short-term use (C)	Compatible
Antihistamines		
Chlorpheniramine	Safe (C)	Discouraged
Diphenhydramine	Safe (B)	Discouraged
Hydroxyzine	Safety unknown (C)	Discouraged
Meclizine	Safe (B)	Probably compatible
Cetirizine	Probably safe (B)	Safety unknown
Fexofenadine	Safety unknown (C)	Compatible
Loratadine	Probably safe (B)	Compatible
Decongestants		
Pseudoephedrine	Discouraged (C)	Probably compatible

G6PD, glucose-6-phosphate dehydrogenase.

www.ketabpezeshki.com 66485457-66963820

weight, and neonatal abstinence syndrome.[13,14,24] Neonatal abstinence syndrome is characterized by CNS hyperirritability and autonomic nervous system dysfunction and a higher mortality in the offspring.[24]

The short-term use of opiates during lactation appears to be safe, but nursing infants should be closely monitored for respiratory depression.[12,13] A case report of the death of a nursing infant whose mother was taking codeine for pain[13,25] and a review of complications of codeine use in nursing mothers prompted the FDA to issue an advisory for codeine use in lactation.

Anesthetics, Sedative-Hypnotics, and Neuromuscular Blockers

General anesthetics, sedative-hypnotics, and neuromuscular blockers are indicated for rapid sequence intubation (RSI). Some anesthetics and sedative-hypnotics are also used for procedural sedation. Most of the data regarding the use of these agents during pregnancy have been obtained from animal studies and from retrospective human data. None of the agents has been consistently associated with congenital malformations.[26-28]

Anesthetics

Etomidate. Etomidate is an ultra-short-acting hypnotic agent that is commonly used for procedural sedation or RSI. It has not been linked to congenital defects in animals even when high doses were used.[13,14,26,27] Similarly, it is not associated with an increase in congenital anomalies in humans.[13,14,26,27] However, newborns of mothers undergoing cesarean section with etomidate were found to have significant reductions in serum cortisol concentrations 1 hour after delivery.[13,14,27,28] The significance of this effect remains unclear. Because etomidate is excreted in milk in very small amounts and decreases rapidly, it is most likely compatible with breast-feeding.[13,14,28]

Ketamine. Ketamine is a rapidly acting dissociative anesthetic that is commonly used in pediatric procedural sedation and may be used in RSI. It is frequently used in obstetrics and has not been associated with fetal developmental malformations.[13,14,26,27] Ketamine has a dose-dependent oxytocic effect and in high doses (>2 mg/kg) has been associated with uterine tetany.[13,14,26,27] It may also result in increased maternal blood pressure and heart rate and an increased neonatal muscle tone.[13,14] Neonatal depression has also been reported.[13,14] Whereas there are no published data on the effects of maternal ketamine use on the nursing infant, the amount of ketamine in the mother's plasma should be undetectable after 12 hours, and the American Academy of Pediatrics (AAP) considers it compatible with breast-feeding when it is used after this time.[12-14]

Midazolam. Midazolam is a short-acting benzodiazepine commonly used in procedural sedation or RSI. It has not been linked to congenital defects in most laboratory animals even when high doses are used.[13,14,26-28] In humans, there are no data available on its use in the first and second trimesters of pregnancy, but benzodiazepines do not appear to result in malformations in human observational studies.[13,14,26-28] When it is used at term, midazolam has been associated with neonatal respiratory depression and decreased muscle tone.[13,14,26-28] The AAP considers midazolam use during lactation of concern because there are few data addressing the issue.[12] However, in a number of studies, the concentration of midazolam in breast milk was found to be negligible 8 hours after maternal ingestion.[13,14,29]

Propofol. Propofol is a rapidly acting sedative anesthetic that is commonly used in RSI and procedural sedation. No data are available regarding its use in the first and second trimesters of pregnancy in humans, but it does not result in malformations in animal studies.[13,14,26,27] Its use at term also appears to be safe, although high doses have been linked to neonatal respiratory and CNS depression.[13,14,26-28] Propofol is thought to be compatible with breast-feeding because only negligible amounts are found in breast milk 24 hours after its use.[13,14,26-29]

Thiopental. Thiopental is an ultra-short-acting barbiturate that may be used during RSI or for status epilepticus. It has not been linked to congenital defects in laboratory animals even when high doses are used.[13,14,26-28] Similarly, it has not been associated with an increase in congenital anomalies in humans.[13,14,26-28] Thiopental is excreted in milk in concentrations that are too low to be pharmacologically significant and is considered compatible with breast-feeding.[12-14]

Neuromuscular Blockers

Nondepolarizing Neuromuscular Blocking Agents. Nondepolarizing neuromuscular blocking agents, such as rocuronium and vecuronium, are used in RSI. The effects of these agents on organogenesis in humans are not known, but these agents are not thought to pose a significant teratogenic risk because very little of the maternal dose crosses the placenta.[13,14,26-28] Furthermore, according to the manufacturers, there was no increase in congenital anomalies noted when small laboratory animals were injected with rocuronium daily.[13,14,26-28] Because of their chemical properties, very little of either drug is excreted in milk.[13,14,26-28] Women are not expected to breast-feed while taking neuromuscular blockers.

Depolarizing Neuromuscular Blocking Agents. Succinylcholine is a depolarizing neuromuscular blocking agent used in RSI for its rapid onset of action and short duration of paralysis. It has not been associated with congenital defects, although there is limited experience with its use in early pregnancy in humans.[13,14,26-28] In addition, it does not appear to have any effects on the newborn, except in rare cases of neonates with pseudocholinesterase deficiency.[13,14,26-28] As occurs in adults with the same condition, newborns with cholinesterase deficiency exhibit prolonged respiratory depression and paralysis.[13,14,26-28] Succinylcholine in lactation has not been studied; however, it is probably safe because it is hydrolyzed quickly.[13,14]

Sedative-Hypnotics

Benzodiazepines. Benzodiazepines are commonly used for the sedation of the acutely agitated patient, in the treatment of acute seizures and alcohol withdrawal, and as a sedative during RSI. The short-term use of benzodiazepines during pregnancy appears to be safe. Case reports have linked their use during the first trimester of pregnancy to increased risk of oral clefts,[10,13,14] but in an observational study based on the Swedish medical birth registry, no such association was found.[13,14,30] Neonates exposed to benzodiazepines may exhibit signs of toxicity, including apnea, cyanosis, unresponsiveness, hypotonia, poor feeding, and withdrawal symptoms characterized by irritability and tremulousness.[10,13,14] Because of the reported risk of apnea, it is recommended that neonates exposed to benzodiazepines through breast-feeding be monitored closely.[10,12-14]

Anticoagulants and Thrombolytics

Warfarin

Warfarin (Coumadin) is a known human teratogen and affects 4 to 5% of exposed fetuses. The risk from exposure is greatest during 6 to 9 weeks of gestation and seems to be dose dependent.[14,15,31] The fetal warfarin syndrome is associated with multiple abnormalities, such as hypoplasia of the nasal bones, midline dysplasia including agenesis of the corpus callosum, optic atrophy

www.ketabpezeshki.com 66485457-66963820

and blindness, mental retardation, seizures, and stippling of the bones with scoliosis and shortening of limbs.[10,14,15,31,32] Because warfarin is so highly protein bound, only a little is secreted into milk, and use by breast-feeding mothers is acceptable.[12-14,31] Caution should be used in breast-feeding of premature infants because they may be at increased risk for intraventricular hemorrhage.[13,31]

Heparin

Unfractionated heparin is a highly charged heterogeneous molecule with a molecular mass between 5 and 35 kDa.[13] It does not cross the placenta and does not present a direct risk to the fetus.[13,14] Early reports on the use of heparin for the prevention or treatment of venous thromboembolism during pregnancy noted an increased risk of prematurity, stillbirth, and fetal hemorrhage.[14] However, these risks were recently attributed to the underlying maternal condition rather than to heparin.[14,15,31,33] When anticoagulation during pregnancy is required, heparin is considered the agent of choice.[13,14,33] Its use is sometimes associated with maternal osteopenia and immune-mediated thrombocytopenia and maternal hemorrhage at delivery.[13,14,31,33] Patients need to be carefully monitored for these adverse effects. Because of its high molecular weight, heparin is not excreted in breast milk and is compatible with breast-feeding, but critically ill patients are not expected to breast-feed.[12-14,31]

Low-molecular-weight heparin may be used during pregnancy and in the postnatal period for therapeutic or prophylactic anticoagulation.[14,15,31,33] All currently available low-molecular-weight heparin products have been used safely during pregnancy.[14,15,31,33] Data are limited, however, because of their relatively recent introduction.

Thrombolytic Agents

Alteplase, reteplase, urokinase, and streptokinase have been used successfully in pregnant women in cases of life-threatening pulmonary embolus[34] or myocardial infarction. Experience with these agents during pregnancy, however, remains limited. To date, no teratogenic effects have been reported in humans, but intrapartum maternal hemorrhage has been reported with alteplase and urokinase.[14,15,31] Most thrombolytics are thought to be compatible with breast-feeding because of their short half-life.[13,14]

Antidotes

N-Acetylcysteine

N-Acetylcysteine is a mucolytic agent that has been used successfully and without untoward effects in pregnant women who have overdosed on acetaminophen.[13-16,35] No teratogenic effects have been reported, and pregnant patients who overdose on acetaminophen should be treated in the same manner as nonpregnant patients are.[13-16,35] Although there are no reports of *N*-acetylcysteine use during lactation, it is most likely safe because it has been used in neonates without untoward effects.[13,14,35]

Deferoxamine

Deferoxamine is indicated for iron toxicity occurring from iron overdose or from multiple transfusions in thalassemia patients. It has been associated with developmental effects on ossification in some animal species.[13,14,35,36] Experience in humans is limited, but it does not appear to affect the fetus.[13,14,35,36] The effects of deferoxamine on the nursing infant are not known, but it is probably compatible.[13,14]

Digoxin Immune Fragment

Digoxin immune fragment (Fab) therapy is indicated for life-threatening digitalis overdose and is being studied for treatment of preeclampsia.[13,14,35] There are very few case reports of the use of digoxin immune Fab during pregnancy, and a conclusion on its effects on the offspring cannot be made.[13,14] Thus in cases of life-threatening digitalis overdose with arrhythmias, the benefits of treatment of the mother outweigh the risk to the fetus. Digoxin immune Fab is not likely to be excreted in large amounts in milk, and it is probably safe for use during lactation.[12-14]

Dimercaprol

Dimercaprol or British antilewisite is a chelating agent that is used as an antidote for acute mercury, lead, arsenic, and gold poisoning.[13,14,35,37] It has also been used in Wilson's disease.[13,14] It is teratogenic in mice and has been associated with increased mortality, growth restriction, cleft facial features, cerebral herniation, and abnormal digits, but experience in humans is limited.[13,14,35,37] In general, in cases of heavy metal poisoning, the maternal benefits of treatment will outweigh the potential risks to the unborn fetus. Breast-feeding is contraindicated in patients poisoned by heavy metals.[13,14]

Flumazenil

Flumazenil is a benzodiazepine antagonist. No teratogenic effects have been reported in animals, and data on humans are limited.[13,14,35] Its use in pregnancy and lactation depends on the potential maternal benefit compared with possible risks to the fetus and nursing infant. Because it has a short half-life, breast-feeding may resume after a few hours.[13,14]

Fomepizole

Fomepizole is a competitive inhibitor of alcohol dehydrogenase indicated in cases of methanol and ethylene glycol poisoning. Its use during pregnancy has not been studied in animals or humans. Its safety during pregnancy is not known.[13,14,35] In cases of toxic alcohol poisoning, the benefits of treatment of the mother outweigh the possible risks to the fetus or nursing infant. Use of ethyl alcohol in these situations may be considered.[13,14] Breast-feeding is not expected to continue during acute toxic alcohol poisoning.

Hydroxycobalamin

Hydroxycobalamin is a vitamin B_{12} derivative that is indicated in the treatment of cyanide toxicity. The effects of hydroxycobalamin on human pregnancy have not been studied, but benefits of its use in cyanide poisoning outweigh any risk to the fetus. Studies in animals do not reveal an association with any developmental abnormality.[13,14] Breast-feeding is not expected to continue during cyanide poisoning, but hydroxycobalamin, like its related compounds, is considered compatible with breast-feeding.[12-14]

Methylene Blue

Methylene blue is used in the treatment of methemoglobinemia. In the past, it was injected into the amniotic sac to identify twins and to detect rupture of the membranes, but these practices were associated with hemolytic disease in the newborn, hyperbilirubinemia, and deep blue staining of the newborn.[13,14,35,38] Methylene blue in pregnancy has also been associated with an increased incidence of intestinal obstruction and atresia in the newborn.[13,14,35,38] Breast-feeding is not expected to continue during acute severe

www.ketabpezeshki.com 66485457-66963820

methemoglobinemia, but the effects of methylene blue on the nursing infant are expected to be minimal.[13,14]

Naloxone

Naloxone, used to reverse severe respiratory depression in opiate overdose, readily crosses the placenta. Although it has not been associated with reproductive abnormalities,[13,14,35] its use during pregnancy results in increased fetal wakefulness, increased fetal movement, and increased heart rate, effects attributable to antagonism of fetal endorphins.[13,14,35] In addition, its use in opiate-addicted mothers may precipitate withdrawal in both mother and term fetus.[13,14,39] It is compatible with breast-feeding.[12-14]

Physostigmine

Physostigmine is an anticholinesterase agent indicated in cases of severe anticholinergic poisoning associated with delirium. Experience with the medication during pregnancy is limited, and its effects on the developing fetus are unknown.[13,14,35] Use of physostigmine at term was associated with only mild decreases of Apgar scores at 1 and 5 minutes.[13,14,40] Breast-feeding is not expected to continue during anticholinergic poisoning, but physostigmine is thought to be probably compatible with breast-feeding.[13,14]

Pralidoxime

Pralidoxime is indicated for organophosphate/cholinergic poisoning because it is able to reactivate cholinesterase. Experience with pralidoxime in pregnancy is limited, and its effects on fetal development are not known.[13,14,35,40] In cases of organophosphate poisoning, the benefits to the mother generally outweigh the possible risk to the fetus. Breast-feeding is not expected to continue during cholinergic poisoning.

Pyridoxine

Pyridoxine is a vitamin required for good maternal health and good fetal development. It is indicated in isoniazid poisoning and in gyromitrin mushroom poisoning. Its use has been advocated by some for nausea and vomiting of pregnancy, gestational hypertension, and diabetes.[13,14] It has not been associated with any adverse developmental effects, and it is safe in lactation.[13,14]

Succimer

Succimer is a heavy metal chelator that is indicated in lead poisoning. It has also been used in arsenic, mercury, and cadmium poisoning. It has been linked to congenital defects in animal models, possibly because of its negative effects on zinc and copper metabolism.[13,14,35] Experience with the use of succimer in human pregnancy is limited to case reports, which did not shed any light on its teratogenicity in humans.[13,14,35,37,41] There are no reports of succimer use during lactation, but breast-feeding is contraindicated in heavy metal poisoning.[13,14]

Antimicrobial Agents

Infections in the pregnant woman have the potential to adversely affect pregnancy outcome as well as fetal development. When they occur in the first trimester, they are a common cause of spontaneous abortion, and when they occur in the second or third trimester, they are the most common cause of preterm labor and delivery. Antimicrobial agents also may adversely affect the pregnancy. Aminoglycosides, for example, may be nephrotoxic and ototoxic in both the mother and her offspring,[13,14,41,42] tetracyclines may result in dental staining of the developing fetus,[13,14,41,42] and lincosamides may be skeletotoxic.[13,14] The penicillins, cephalosporins, and macrolide antibiotics remain the drugs of choice for infections during pregnancy.[41,42] Other classes of antibiotics are prescribed only if these have failed to control the infection or in cases of severe maternal intolerance to these drugs.[13,14,41,42] The choice of antimicrobial therapy will depend on the age of the pregnancy, severity of infection, and maternal tolerance for the drug used. Many drugs also are secreted into breast milk. Potential problems for the neonate include direct effects on the neonate, changes in bowel flora, diarrhea, and potential interference with culture results.[12-14]

Antibiotics

Aminoglycosides. The association of aminoglycosides such as gentamicin, streptomycin, tobramycin, and neomycin with nephrotoxicity and ototoxicity is well known in the literature and in practice.[13,14,41,42] Aminoglycosides, however, do not appear to have any structural teratogenic effect in humans,[43] but kanamycin and streptomycin have been reported to cause ototoxicity in the mother and her offspring.[13,14] There are no reports definitively linking in utero exposure to gentamicin, streptomycin, tobramycin, and neomycin to either ototoxicity or nephrotoxicity.[13,14] Aminoglycosides are secreted in small amounts in breast milk and are poorly absorbed from the gastrointestinal tract.[12-14] They are probably compatible with breast-feeding.[12-14]

Cephalosporins. The first- to fourth-generation cephalosporins appear to be safe for use during pregnancy, although there are no controlled studies examining their safety.* Some cephalosporins are excreted into breast milk and may interfere with culture results in the workup of neonatal sepsis.[13]

Chloramphenicol. Chloramphenicol is a broad-spectrum antibiotic with excellent blood-brain barrier penetration. It remains the drug of choice for meningitis in many developing countries, but it has been associated with bone marrow suppression and aplastic anemia,[13,14,42] which may be fatal. Outside of these complications, its use during pregnancy appears to have no effects on the developing fetus.[13,14,31] However, when it is used at term, chloramphenicol has been associated with cardiovascular collapse in the neonate (the "gray baby" syndrome),[13,14,31,41,42] prompting its contraindication at term. The safety of chloramphenicol during breast-feeding is unknown; however, because of its potential for bone marrow depression and its association with gray baby syndrome, it is not recommended for use during lactation.[12-14]

Clindamycin. Clindamycin has not been associated with birth defects in humans, and animal studies have failed to link clindamycin to congenital abnormalities in the offspring.[13,31,41,42] The AAP considers clindamycin to be compatible with breast-feeding.[12-14] However, this recommendation is not echoed by other agencies because of its rare association with bloody diarrhea in the nursing infant.[13,14]

Fluoroquinolones. Fluoroquinolones have been linked to numerous toxic effects on bone and cartilage growth in animal models and are discouraged from use during pregnancy, particularly during the first trimester.† A number of observational studies, however, have failed to demonstrate such a toxic effect on the human fetus.[13,14,31] Furthermore, a recent meta-analysis did not reveal any increase in the rates of spontaneous abortions, birth defects, prematurity, or low birth weight in women exposed to fluoroquinolones in the first trimester.[44] The AAP considers ciprofloxacin to be compatible with breast-feeding because breast-fed infant plasma levels are low.[12-14] Data are inconsistent for other quinolones, and they are best avoided in lactation.

Linezolid. Linezolid is effective in the treatment of methicillin-resistant *Staphylococcus aureus* infection. It has been linked to

*References 11, 13, 14, 31, 41, 42.
†References 10, 13, 14, 31, 41, 42.

www.ketabpezeshki.com 66485457-66963820

embryonic death, decreased weight, and abnormalities in cartilage and ossification in animal studies,[13,14] but there is no information about its effects in humans. Its use in pregnant women should be limited to cases in which the maternal benefits outweigh possible risks to the fetus.[13,14] Linezolid is excreted into breast milk, but the amount that reaches the nursing infant appears to be small, and it is likely to be compatible with breast-feeding.[13,14]

Macrolides. Erythromycin, azithromycin, and clarithromycin are considered to be safe for use in pregnancy and compatible with breast-feeding, although there are no well-controlled studies examining their effects on the fetus.[13,14,31,41,42] Some reports have linked erythromycin to pyloric stenosis, but the studies were not controlled.[13,14,31,41,42] The estolate salt of erythromycin has also been associated with the development of hepatotoxicity in pregnant women and should be avoided during pregnancy.[13,14,31] Clarithromycin has been associated with an increased risk of fetal and embryonic death as well as with congenital malformations in animal species.[13,14] To date, however, this has not been shown in humans. For example, in a prospective controlled multicenter observational study comparing the outcomes of pregnancies exposed to new macrolides (including clarithromycin) with matched controls, no difference in the types or patterns of malformations between the groups was found.[13,14,45] Azithromycin is poorly concentrated in breast milk and may be the preferred agent in lactating mothers.[12-14]

Metronidazole. Metronidazole is indicated for the treatment of anaerobic infections, amebiasis, *Clostridium difficile* infection, and bacterial vaginoses. It is mutagenic and carcinogenic in mice and rats.[13,14] In humans, a number of studies failed to demonstrate a clear association between metronidazole use and congenital malformations when it was used in the first trimester of pregnancy.[13,14,35,46] Metronidazole has also been frequently used during the second and third trimesters to treat bacterial vaginosis with no untoward effects.[13,14] However, because of its effects in mice, many physicians avoid prescribing it at all during pregnancy.[13] Use of metronidazole during lactation is discouraged because of its potential mutagenic and carcinogenic effects in rats and its slow elimination from infants.[12-14]

Nitrofurantoin. Nitrofurantoin is commonly used for the treatment of uncomplicated urinary tract infections and has traditionally been considered safe for use throughout pregnancy except near term. However, a population-based multicenter case-control study linked its use in the first trimester to a number of congenital abnormalities, including anencephaly, microcephaly, hypoplastic left heart, atrial septal defects, and craniofacial clefts.[42] Its use near term has been associated with hemolytic anemia in the newborn.[13,14,31,47]

Penicillins. The first- to fourth-generation penicillins and their derivatives (including procaine, benzathine, clavulanate, sulbactam, and tazobactam) are considered safe for use in pregnancy, as is oral probenecid.[13,14,31,41,42] Penicillins are considered safe during breast-feeding, but their use may interfere with culture results if workup is required for a neonatal fever.[12,13]

Sulfonamides. Sulfonamides are used in the treatment of uncomplicated urinary tract infections and are indicated in the treatment of *Pneumocystis jiroveci* (formerly known as *Pneumocystic carinii*) pneumonia. They are also effective against methicillin-resistant *S. aureus*. Sulfamethoxazole is commonly combined with trimethoprim, presumably to improve antimicrobial efficacy. Both are folic acid synthesis inhibitors and have traditionally been contraindicated in pregnancy because of an increased risk of neural tube defects[13,14,31] and other congenital abnormalities, such as cleft palate.[13,14,31,41,42] A number of observational studies have demonstrated an increased risk of cardiovascular and urinary tract malformations in the offspring of women treated with trimethoprim-sulfamethoxazole in the first trimester.[42,48] Sulfonamides are contraindicated near term because of their association with kernicterus.[13,14,41,42] They compete with bilirubin for protein-binding sites, leaving large amounts of free bilirubin to diffuse freely into the brain. This results in bilirubin deposition in the infant's brain, causing kernicterus. To date, however, this complication has not been reported in neonates, presumably because free bilirubin is effectively cleared by the placental circulation.[13,14] In contradistinction, kernicterus has occurred in newborns exposed to sulfonamides after birth.[13,14] Sulfonamides are excreted into breast milk in low concentrations and are generally tolerated by a healthy neonate.[12-14] They should be avoided, however, in ill or premature infants and in infants with hyperbilirubinemia or glucose-6-phosphate dehydrogenase deficiency.[12-14]

Tetracyclines. Tetracyclines are effective in a number of infections, including infections with atypical bacteria, *Yersinia pestis* infection, and anthrax. Both tetracycline and doxycycline readily cross the placenta.[13,14,31] Tetracycline, but not doxycycline, has been associated with the development of fatal fatty liver in pregnant women.[13,14,31] Tetracycline also chelates calcium, causing abnormalities in bone growth and staining of decidual teeth.[13,14,31,41,42] It has also been associated with fetal genitourinary anomalies, inguinal hernias, and limb abnormalities.[13,14,31,41,42] Tetracycline should therefore be avoided during pregnancy. Doxycycline, on the other hand, does not bind to calcium and is associated less with stained teeth than is tetracycline.[13,14,31] In addition, it does not appear to cause an increase in any type of congenital malformation.[13,14,31] Despite these findings, doxycycline is not recommended in pregnancy.[13,14,31,42]

Because tetracycline binds to breast milk calcium, only a small amount reaches the nursing infant, and it may be used for short periods (<10 days) during breast-feeding.[13,14,31] Doxycycline does not bind to breast milk calcium and is present in greater quantities in breast milk.[12-14] This could theoretically increase its side effects in the newborn. Its use in nursing infants is best avoided.[12-14,31]

Vancomycin. Vancomycin is effective against methicillin-resistant *S. aureus* and *C. difficile*. It has not been linked to birth defects in animals or in humans.[13,14,31,49] Reports of auditory abnormalities and renal insufficiency in neonates of mothers treated with vancomycin are believed to be false positives because these abnormalities were resolved on retesting.[13,14] Vancomycin is excreted into milk but not well absorbed by the gastrointestinal tract.[12-14,31] Its effects on the nursing infant have not been studied.[12-14,31]

Antifungal Medications

Nystatin has a long safety profile during pregnancy and lactation. It is poorly absorbed from skin, mucous membranes, and the gastrointestinal tract, and it is considered the antifungal agent of first choice for treatment of mucocutaneous fungal infections.[13,14,31] Clotrimazole, miconazole, and ketoconazole seem to be safe during pregnancy and lactation as they have not been associated with major birth defects.[13,14,31] However, a minor increase in the incidence of hypoplastic left ventricle was reported in one case-control study.[13,14,31,50] In addition, ketoconazole is teratogenic in rats.[13,14,31,50] For these reasons, clotrimazole, miconazole, and ketoconazole are considered second-line treatment of fungal infections in pregnancy.[13,14,31,50] Fluconazole is teratogenic in high doses (>400 mg/day) and has been associated with an increased incidence of craniofacial and cardiovascular defects in offspring and multiple abnormalities of the skeleton and cartilage.[13,14,31,50] These anomalies were not noted when lower doses were used or with single-dose (150 mg) therapy for vaginal candidiasis.[13,14,31,50]

Ketoconazole, fluconazole, and itraconazole are excreted into breast milk.[12-14] On the basis of the safe use of ketoconazole in

www.ketabpezeshki.com 66485457-66963820

neonates and the lack of negative reports, it is considered compatible with breast-feeding.[12-14]

Antituberculous Agents

Untreated tuberculosis places the mother and fetus at greater risk than does the use of antituberculous medications. Isoniazid, ethambutol, and rifampin cross the placenta,[13,14,31] and in a review of antituberculous treatment during pregnancy, no association was found between these medications and major congenital malformations.[13,14,51] Rifampin has been associated with hemorrhagic disease of the newborn.[13,14,51] Despite this adverse effect, it maintains its first-line quality in the treatment of tuberculosis.[13,14,51] All three antituberculous medications are considered compatible with breast-feeding.[12,13,51]

Antiviral Agents

Antiherpetic Drugs. Acyclovir is a purine analogue commonly used in the treatment of herpesvirus infections. Valacyclovir is rapidly metabolized to L-valine and acyclovir, the active metabolite.[13,14] In humans, acyclovir readily crosses the placenta and reaches higher concentrations in fetal circulation than in maternal circulation.[13,14] Neither acyclovir nor valacyclovir has been associated with congenital malformations or adverse effects on the offspring.[13,14,52] Intravenous acyclovir is the drug of choice for life-threatening maternal herpes simplex virus infections,[13,14,53] such as disseminated disease, herpes encephalitis, and varicella pneumonia, which carries a maternal mortality of 44% if it is untreated.[13,14,53] For non–life-threatening genital herpes infection in pregnant women, either acyclovir or valacyclovir may be used.[13,53,54] Experience with famciclovir is limited and it is therefore not recommended for use in pregnancy.[13,14,52] Acyclovir is concentrated in milk, in which levels may be higher than in plasma.[12-14] Because there are no reported adverse outcomes in infants of mothers taking acyclovir or in infants treated with acyclovir for disseminated herpes, it is considered safe during breast-feeding.[12-14]

Anti-Influenza Drugs. Influenza in pregnancy carries a high risk of morbidity and mortality. During the 2009-2010 H1N1 pandemic, 6% of confirmed H1N1 deaths in the United States occurred in pregnant women.[55] Antiviral therapy with either M2 ion channel inhibitors, such as amantadine and rimantadine, or neuraminidase inhibitors, such as oseltamivir and zanamivir, is associated with improved maternal and pregnancy outcomes.[13,14,56,57] Whereas amantadine had been linked to various malformations including cardiac defects in humans and is considered teratogenic and embryotoxic in rats,[13,14] a cohort study found that neither class of anti-influenza drugs was associated with an increase in malformations or stillbirths.[13,57] There was, however, an increase in the incidence of necrotizing colitis in premature newborns exposed to either of these classes of drugs.[13,14] Oseltamivir appears safe in lactation.[13,14]

Anti-HIV Drugs. Anti-HIV drugs may be indicated immediately after a needle-stick injury or sexual contact with an infected individual. No specific pattern of birth defects has been described with the use of these drugs,[13,14] but there are a number of unanswered questions relating to the drugs' mutagenesis and carcinogenesis and their long-term effects on the liver, heart, and reproductive system.[13,14]

Animal and human data suggest that didanosine, lamivudine, stavudine, zidovudine, and zalcitabine present a small risk of structural malformations and mitochondrial dysfunction in the developing fetus,[13,14] but no specific pattern of birth defects has been described with protease inhibitors, such as ritonavir and nelfinavir.[13,14] Despite potential risks, it is thought that the benefit from treatment of HIV infection far outweighs the risk of these drugs, and treatment should not be withheld. In addition, zidovudine has been shown to significantly reduce vertical and perinatal transmission of HIV from the mother to the fetus.[13,14,53,58] Because of the risk of postnatal HIV transmission through milk, the Centers for Disease Control and Prevention advises against breast-feeding by HIV-positive mothers.[53]

Cardiovascular Agents

Antidysrhythmics

Atrial and ventricular arrhythmias are common during pregnancy. Most are benign; however, malignant degeneration occasionally occurs.[59-62] All unstable tachycardias should be treated with electrical cardioversion and according to advanced cardiac life support guidelines.[59-62] Stable patients may be treated medically, but the choice of drugs needs to be modified to protect the patient as well as the fetus from the drug's harmful effects.[59-62]

Adenosine. Adenosine is a naturally occurring compound that is metabolized quickly in the body. It has been used safely throughout pregnancy and is the drug of choice for termination of maternal supraventricular tachycardia.[13,14,59-62] Adenosine has also been used safely in termination of incessant tachycardia in the fetus.[13,14,59-62] Adenosine is safe in lactation.[12-14]

Amiodarone. Amiodarone is a class D agent. It contains large amounts of iodine and has been associated with congenital goiter and transient neonatal hyperthyroidism and hypothyroidism.[13,14,59-63] In addition, amiodarone has been linked to many congenital abnormalities, including growth restriction, structural cardiac abnormalities, corneal deposits, and developmental delay.[13,14,59-63] It should be used only in refractory cases of supraventricular or ventricular tachycardias in the mother and incessant tachycardias in the fetus.[13,14,59-63] Because of its high iodine content, its excretion into milk, and its long elimination half-life, amiodarone should not be used in nursing mothers.[12-14,31]

Digoxin and Quinidine. Digoxin and quinidine are considered safe for use during pregnancy and lactation.* Neither has been linked to congenital defects in humans or animals, and they are first-line agents for the treatment of significant maternal dysrhythmias.* They have also been successfully used in fetal tachycardia.* Overdoses of these drugs, on the other hand, have led to premature labor, spontaneous abortions, and, in the case of digoxin, fetal death.[13,14] During lactation, digoxin appears compatible with breast-feeding; there is very little information about quinidine's use in breast-feeding.[12-14]

Lidocaine. Lidocaine is a weak base. It rapidly crosses the placenta and becomes ion trapped in the fetus.[13,14] There is no evidence of a link between use of lidocaine in the first trimester and any fetal developmental malformations.[13,14,31,59-61] However, high doses used near term are associated with neonatal CNS depression, apnea, hypotonia, seizures, and bradycardia.[13,14,59-61] Lidocaine is considered compatible with breast-feeding.[12-14]

Procainamide. Procainamide has been successfully and safely used in the treatment of stable wide-complex tachydysrhythmias during pregnancy.[59-62] It has not been associated with fetal developmental abnormalities and appears well tolerated when it is used for short durations.[13,14,59-62] It has been associated with a high incidence of maternal antinuclear antibodies and the occurrence of a lupus-like reaction in humans.[13,14,31] During lactation, both procainamide and its metabolite, *N*-acetylprocainamide, have been found in breast milk,[13,14] and although the AAP considers its short-term use compatible with breast-feeding,[12] other authorities do not recommend it.[13,14]

Flecainide. Flecainide is a class IC antiarrhythmic agent that is structurally related to procainamide.[13,14] It has been used safely to

*References 13, 14, 31, 59, 60, 62.

www.ketabpezeshki.com 66485457-66963820

terminate maternal and fetal tachycardia,* but it has been associated with fetal hyperbilirubinemia, hepatotoxicity, and loss of fetal heart rate variability.* Flecainide has also been found to be teratogenic in some animal species, resulting in cardiac and musculoskeletal abnormalities.* Flecainide is found in breast milk, but apparently in concentrations that are not toxic to infants.[12-14] The AAP considers flecainide compatible with breast-feeding despite limited experience.[12,13]

Ibutilide. Ibutilide is a class III antiarrhythmic used to terminate atrial fibrillation and flutter. There are only a few case reports of its successful and safe use during the latter part of pregnancy in humans.* In animals, however, ibutilide was found to be teratogenic and caused cardiac septal defects as well as skeletal dysgenesis in rats,[13,14] especially when high doses were given. Ibutilide should be reserved for refractory cases in which the benefits of therapy outweigh any fetal risk.[13,14]

Sotalol. Sotalol has been used in pregnant women to successfully and safely treat atrial arrhythmias as well as hypertension.[59-62] It has also been successfully used to terminate fetal atrial tachycardias.[59-62,64] It does not appear to have teratogenic effects in animals.[13,14] Some of the negative effects of sotalol include bradycardia in the newborn, persisting for 24 hours.[13,14] Sotalol is concentrated in milk but does not appear to result in bradycardia or hypotension in the nursing infant, and according to the AAP it is compatible with breast-feeding.[12-14]

Antihypertensives

Hypertension complicates 12% of pregnancies and is most commonly seen in the third trimester.[65] It accounts for 16% of maternal deaths in the United States.[65] Labetalol is the agent of choice for hypertensive emergencies in pregnancy.[66-68]

Angiotensin-Converting Enzyme (ACE) Inhibitors. ACE inhibitors are classified as category D drugs and are contraindicated for use during pregnancy.[13,14,69] Furthermore, ACE inhibitors are embryocidal in animals and increase the rate of stillbirths in some animal species.[13,14] In humans, the most significant adverse fetal effects occur when they are used in the second and third trimesters.[13,14,66-69] These include oligohydramnios, anuria, renal agenesis resulting in death, increased risk of stillbirth, intrauterine growth restriction, fetal skull abnormalities, pulmonary hypoplasia, respiratory distress syndrome, and fetal and neonatal hypotension.[13,14,66-69] Captopril and enalapril are considered compatible with breast-feeding.[12-14,68]

Angiotensin II Receptor Antagonists. Angiotensin II receptor antagonists should be avoided during pregnancy because their use has been reported to result in fetal abnormalities similar to the abnormalities seen with ACE inhibitors, including renal agenesis, neonatal anuria, oligohydramnios, intrauterine growth restriction, persistent patent ductus arteriosus, abnormal ossification, and death.[13,14,66-69] Their safety in lactation is unknown.

Beta-Blockers. Beta-blockers have become a first-line treatment of hypertension in pregnancy.[70,71] They have not been associated with fetal malformations and appear to be safe when they are used for short periods.† Adverse fetal effects include intrauterine growth restriction and a low placental weight.† Beta-blockers lacking intrinsic sympathomimetic activity, such as acebutolol, atenolol, nadolol, and propranolol, are more likely to be associated with these adverse effects.† When beta-blockers are given near term, they have been associated with persistent beta blockade in the newborn.† Nonselective beta-blockers, such as propranolol, also have resulted in neonatal hypoglycemia, respiratory depression, and hyperbilirubinemia in the newborn.* These adverse effects are less common when a cardioselective beta-blocker, such as atenolol or metoprolol, is used.* Esmolol, a short-acting beta-blocker commonly used to terminate maternal supraventricular dysrhythmias and hypertension during surgery, has been associated with fetal bradycardia, neonatal bradycardia and hypotonia, and fetal distress requiring emergent cesarean section.* Beta-blockers have variable effects on the nursing infant, and close monitoring of the infant for adverse effects is recommended.[12-14,68]

Calcium Channel Blockers. Calcium channel blockers have been used for the treatment of hypertension and the termination of supraventricular rhythm disturbances during pregnancy.† Intravenous verapamil has also been used to terminate fetal tachycardia,† and intravenous nicardipine has been used for severe preeclampsia.† In addition, some calcium channel blockers, such as nifedipine and diltiazem, have been used as tocolytic agents.[13,14,31] In laboratory animals, use of calcium channel blockers in the first trimester was associated with a dose-dependent increase in embryonic mortality and skeletal abnormalities.[13,14,31] To date, however, these abnormalities have not been seen in humans, although data remain limited.[13,14,66-68] A prospective multicenter observational study of 299 patients exposed to calcium channel blockers in the first trimester did not reveal an increase in congenital malformations compared with controls.[71] Some complications of calcium channel blocker use during pregnancy include maternal hypotension, tachycardia, and fetal distress,† especially pronounced when sublingual nifedipine or intravenous nicardipine is used.[13,14] The AAP considers these drugs compatible with breast-feeding.[12,13,31]

Clonidine has been safely used in the treatment of severe hypertension throughout pregnancy, but experience during the first trimester remains limited.[13,14,66-68] It does not appear to be teratogenic in laboratory animals and does not increase fetal mortality.[13,14] Transient neonatal hypertension has been reported in neonates.[4,14,66-68] Its effects on breast-feeding neonates are unknown, but it is considered to be compatible with breast-feeding.[12-14,68]

Hydralazine is a direct vasodilator that has a rapid onset of action. Its use, however, has been associated with higher rates of maternal hypotension, placental abruption, and neonatal distress compared with labetalol.‡ It is therefore no longer recommended as a first-line agent in the treatment of severe acute hypertension in pregnancy. It may still be used as a second-line agent.[66-68,73] Hydralazine is considered compatible with breast-feeding.[12-14,68]

Methyldopa has been safely used to treat chronic hypertension throughout pregnancy, and most reviews have not linked it to any teratogenic effects on the offspring or adverse effects on the pregnancy.[13,14,31,66-68] Many clinicians continue to prescribe it as first-line therapy for hypertension during pregnancy. Methyldopa is compatible with breast-feeding.[12-14,68]

Diuretics. Diuretics are no longer used for gestational hypertension or preeclampsia because, in general, affected patients tend to be hypovolemic.[13,66-68]

Loop diuretics such as furosemide are indicated in the treatment of pulmonary edema due to congestive heart failure. In laboratory animals, furosemide has been linked to renal and skeletal abnormalities when it is used in pregnancy.[13,14] These effects have not been seen in humans, but a slightly increased risk of hypospadias has been reported.[13,14] Furosemide is secreted into breast milk but is considered compatible with breast-feeding.[12-14]

Thiazide diuretics have been associated with hypoglycemia and electrolyte abnormalities in neonates when they are given near term and an increase in meconium staining and perinatal

mortality.[13,14] Moreover, thiazide diuretics may have a direct effect on smooth muscle and inhibit labor.[13,14] In general, these agents are excreted in low quantities into breast milk and are considered safe during breast-feeding.[12-14]

Nitrates. Nitroglycerin has not been shown to cause fetal harm in animal studies.[13,14,31] Limited reports in humans do not show any major effects on the fetus or neonate.[13,14,31] Nitroglycerin is rarely used during pregnancy, but it appears to be a safe, effective, rapidly acting and short-acting agent.* It appears to be effective in relieving intrapartum fetal distress related to uterine hyperactivity.[76] Nitroprusside for the treatment of hypertensive emergencies in pregnancy has the same advantages and disadvantages as in nonpregnant patients. During prolonged administration of high doses, nitroprusside may result in cyanide toxicity and severe acidosis.[13,14,74,75] It readily crosses the placenta, and fetal levels of cyanide can increase as high as twice maternal levels.[13,14,74,75] Standard doses do not seem to subject the fetus to major risk of toxicity,[13,14] but with the availability of safer alternatives, notably labetalol, nitroprusside is considered a last-resort agent.† No data are available on its use during lactation, but breast-feeding is not expected to continue during critical illness.

Vasopressors

Vasopressors are indicated in shock states only after intravascular volume has been restored. Whereas they are effective in restoration of intravascular resistance and blood pressure, all have the potential to increase uterine vascular resistance, resulting in a proportional decrease in placental blood flow.[74,75,77,78] Each of the vasopressors has its indications, its benefits, and its inherent risks. At this time, on the basis of its safety profile, phenylephrine appears to be the vasopressor of choice in the treatment of vascular collapse during pregnancy.[74,75,77,78]

Dobutamine. Dobutamine is an inotrope used in the setting of cardiac dysfunction and sepsis.[74,75] It has not been associated with any negative reproductive effects in laboratory animals or in humans.[13,14]

Dopamine. Dopamine has a dose-dependent effect on dopaminergic, alpha, and beta receptors and has been used in maternal shock, including spinal shock due to spinal anesthesia.[13,14,74,75] Low-dose dopamine has been successfully used to improve cardiac and urine output in patients with preeclampsia and oliguria,[74,75] but this has not been shown to improve mortality or renal function.[79] No significant fetal side effects have been directly linked to its use in animal studies, even though it has been shown to decrease uterine vascular flow.[13,14] Its safety during breast-feeding has not been studied, but breast-feeding is not expected to continue during critical illness.[12,13]

Epinephrine. Epinephrine is the preferred agent for the treatment of anaphylaxis and is commonly used in status asthmaticus. It has also been used to treat shock from any cause during pregnancy.[13,74,75] However, it has been associated with anoxic injury to the fetus, intracranial hemorrhage, and increased incidence of inguinal hernias.[13,14,74,75] Safety during breast-feeding has not been studied.[12,13]

Norepinephrine. Norepinephrine use during pregnancy has been associated with the occurrence of vascular and skeletal abnormalities in rodents and a significant decrease in placental blood flow and fetal oxygenation.[13,14] It has also been associated with increased incidence of cerebral hemorrhage.[13,14,74,75] Its safety during breast-feeding has not been studied,[13] but breast-feeding is not expected to continue during critical illness.[12,13]

Ephedrine and Phenylephrine. Ephedrine and phenylephrine are both effective in the treatment of shock from any cause in pregnancy.[74,75,77] Compared with phenylephrine, ephedrine was associated with higher heart rates, more maternal gastric upset, and greater incidence of fetal acidosis.[13,14,74,75,77] Ephedrine is no longer the agent of choice in shock during pregnancy as it has been replaced by phenylephrine.[77]

Endocrine Agents

Diabetes Medications

Diabetes mellitus is associated with a number of congenital malformations involving multiple organ systems.[13,14,78] It is also associated with a significant increase in perinatal morbidity.[13,14,78] Glycemic control in pregnancy is therefore important and should be accomplished in a controlled manner as hypoglycemia is also associated with adverse pregnancy outcomes.[13,14,78]

Insulin. Insulin is a large peptide that does not cross the blood-placenta barrier. It is considered to be the drug of choice in the United States for diabetes mellitus types 1 and 2 in pregnancy.[13,78]

Sulfonylureas. Sulfonylureas are regarded as possibly teratogenic and less effective than insulin in the control of gestational diabetes.* They have also been associated with neonatal hypoglycemia with use at term.* In reality, outside the perinatal period, there is little information about their use during pregnancy, and in a randomized study, glyburide proved to be as effective and safe as insulin during pregnancy.[80] Glyburide and glipizide are highly protein bound and are not likely to pass into breast milk; nursing infants should nevertheless be monitored.[12,13,78]

Metformin. Metformin has been associated with serious adverse effects in adults, including life-threatening metabolic acidosis and hepatotoxicity.[13,14,78] It has not been associated with fetal malformations in animals,[13,14,31,78] and there were no major birth defects in women taking metformin for polycystic ovary disease in a 2004 report.[13,81] In addition, metformin does not appear to result in neonatal hypoglycemia, a complication commonly seen with the use of sulfonylureas at term.[13,14,78,81] In the developing world, where the administration of insulin may be problematic, metformin is a good alternative to insulin for type 2 diabetes mellitus when diet alone is not effective.[13,81] Whereas metformin is considered compatible with breast-feeding by the AAP,[12] it should be used with caution in lactating mothers because of its potential for serious effects in adults and its excretion into milk.[13]

Thyroid Medications

Maternal hyperthyroidism is associated with an increased risk of spontaneous abortion, preterm labor, placental abruption, and maternal congestive heart failure. Effects of the disease on the offspring include intrauterine growth restriction, intrauterine fetal death, and neonatal goiter.[13]

Propylthiouracil (PTU). PTU, the drug of choice during pregnancy, prevents the synthesis of thyroid hormone and prevents the peripheral conversion of T_4 to T_3.[13,31] Complications of treatment include transient goiter and hypothyroidism of the newborn.[13,82] There does not appear to be an increase in the risk of congenital defects with PTU.[13,14,31,82] Other drugs used to control hyperthyroidism in pregnancy include methimazole and carbimazole, both of which have been associated with abnormal development of the skin, albeit inconsistently.[13,14,31,82] PTU is excreted into breast milk in insignificant amounts and is considered compatible with breast-feeding.[12,13]

*References 13, 14, 31, 74, 75.
†References 13, 14, 66-68, 74, 75.

*References 13, 14, 31, 78, 80.

www.ketabpezeshki.com 66485457-66963820

Iodides. Iodides are reserved for thyrotoxic patients. These agents are readily taken up by the fetal thyroid gland, resulting in prolonged fetal hypothyroidism and goiter.[13,14]

Levothyroxine. Hypothyroidism in pregnancy may result in an increased risk for spontaneous abortion, intrauterine growth restriction, placental abruption, and fetal demise and has been associated with severe neurologic impairment of the offspring.[13,14] Levothyroxine, a synthetic formulation of naturally occurring T_4, has not been associated with any negative effects on the offspring and is the treatment of choice for hypothyroidism in pregnant women.[13,14,31] It is compatible with breast-feeding.[12,13]

Gastrointestinal Agents

Antacids

H_2 Receptor Antagonists. Antacids are commonly prescribed throughout pregnancy. None of the H_2 receptor antagonists has been linked to congenital malformation, and they all appear to be safe for the nursing infant.[13,14] There is one report in the literature, however, linking in utero gastric suppression to an increased incidence of asthma during childhood.[13,14,83]

Proton Pump Inhibitors. Despite the limited size of most studies on proton pump inhibitor use in pregnancy, a meta-analysis found no association with an increased risk for major congenital birth defects, spontaneous abortions, or preterm delivery.[84] Proton pump inhibitors, such as esomeprazole, lansoprazole, pantoprazole, and rabeprazole, are accepted for use during pregnancy.[13,14] There are reports, however, of an increased incidence of gastrointestinal, hepatic, and thyroid cancers in rats and mice.[13,14] There are no human data studying the effect of proton pump inhibitors on nursing infants.[12,13]

Antiemetic Medications

Phenothiazines. Phenothiazines, such as metoclopramide, prochlorperazine, and promethazine, are dopamine antagonists commonly used in the treatment of nausea and vomiting during pregnancy. Although there are reports of increased risk of cardiac defects,[13,14] these reports did not consider other factors, such as the mother's health, when the drug was reviewed. The bulk of evidence does not support a link to congenital abnormalities.[13,14,85] These agents are excreted in milk. The AAP cautions against their use in nursing mothers as they may cause sedation and other untoward effects.[12,13]

Serotonin 5-HT$_3$ Receptor Antagonists. Dolasetron, granisetron, and ondansetron have not been linked to any fetal malformations,[13,14,85] although experience with the newer agents remains limited.[13,14,85] The AAP considers these agents compatible with breast-feeding.[12,13]

Neurologic Agents

Anticonvulsants

Anticonvulsants are known teratogens, and 30% of neonates exposed to commonly used anticonvulsants exhibit congenital anomalies.* The risks for birth defects increase with the duration of exposure and with the number of agents used.[86,87] Valproate is associated with the most frequent serious adverse effects on the pregnancy and fetus (20.3% incidence of serious adverse outcomes) compared with phenytoin, carbamazepine, and lamotrigine (10.7%, 8.2%, and 1.0%, respectively).[13,86,87] Despite the risks, most practitioners believe that it is important to control seizures during pregnancy. Generalized seizures during pregnancy are associated with an increased risk of spontaneous abortion, hypoxic injury to the fetus, and impaired neuropsychological functioning.[13,31]

*References 13, 14, 31, 86, 87.

Monotherapy is the most appropriate option and is recommended at the lowest effective anticonvulsant dose.[13,31,86,87] Dividing of the daily dose to decrease peak plasma levels may be considered. Adjustment of the dosage upward is often required to maintain adequate seizure control.[13,31,86,87]

Classic Anticonvulsants. The classic anticonvulsants are considered class D agents and are teratogenic.* Carbamazepine has been linked to an increased risk of craniofacial defects, neural tube defects, and developmental delay.* Phenobarbital has been associated with a slightly increased risk of congenital heart disease and cleft lip or palate.* In addition, its chronic use during pregnancy has been associated with neonatal withdrawal.* Phenytoin use during pregnancy has been associated with the fetal hydantoin syndrome, which affects 5 to 10% of pregnancies.* This syndrome is characterized by varying degrees of ossification abnormalities of the extremities and digits, craniofacial abnormalities including cleft lip and palate, impaired growth, delayed neurologic development, and multiple cardiovascular anomalies.* Valproic acid is associated with multiple facial anomalies, neural tube defects, strabismus, and congenital heart defects.*

Carbamazepine, phenobarbital, and phenytoin have also been associated with hemorrhagic disease of the newborn, presumably because they competitively inhibit placental transport of vitamin K.[13,14,31]

Carbamazepine, phenytoin, and valproic acid are secreted into breast milk in low quantities and are considered compatible with breast-feeding.[11-14] Phenobarbital, on the other hand, has been associated with neonatal sedation and toxicity and is not advised during breast-feeding.[11-14]

Newer Anticonvulsants. Newer anticonvulsants, such as lamotrigine, levetiracetam, and topiramate, have been associated with a slightly increased incidence of major birth defects, such as oral clefts, skeletal abnormalities, and hypospadias.[13,14,86,87] The incidence of these birth defects increases significantly when these substances are combined with other anticonvulsants, such as valproic acid.[13,31,86,87] These findings, however, were not seen in two studies comparing the newer anticonvulsants.[88,89] In the lamotrigine pregnancy registry,[88] a study conducted by the manufacturer of lamotrigine, and in an observational study from Denmark,[89] first-trimester exposure to lamotrigine, oxcarbazepine, topiramate, gabapentin, or levetiracetam was not associated with an increased risk of major birth defects.

These agents also appeared to be well tolerated by the nursing infant, except for topiramate, which caused excess sedation.[13,31]

Migraine Medications

Ergot Alkaloids. Ergotamine and dihydroergotamine are commonly used in the treatment of migraines. Whereas neither has been associated with teratogenic effects, they are contraindicated in pregnancy because of their oxytocic effects[13,14] and their effects on uterine blood flow.[13,14] In a number of animals, these alkaloids have been associated with intrauterine growth restriction, probably because of reductions in uteroplacental blood flow.[13,14] They are also contraindicated during breast-feeding because of possible ergot poisoning of the nursing infant manifested by convulsions and gastrointestinal symptoms.[12-14]

Triptans. The triptans are selective serotonin agonists that are effective in the treatment of vascular headaches, including migraines and cluster headaches. They have been found to be

*References 13, 14, 31, 86, 87.

www.ketabpezeshki.com 66485457-66963820

teratogenic in a number of animal species,[13,14] but recent data in humans appear to favor their safety during pregnancy.[90] Sumatriptan is excreted into milk, but oral bioavailability appears to be low, and very little reaches the nursing infant.[13,14] It is considered compatible with breast-feeding, especially if the milk is discarded for 8 hours after the last dose.[12,13]

Respiratory Agents

Antihistamines

Antihistamines including chlorpheniramine, diphenhydramine, doxylamine, hydroxyzine, and meclizine have been safely used in the treatment of allergic reactions during pregnancy and as antiemetics in the treatment of nausea and vomiting during pregnancy.[13,14,31] This has been further confirmed in recent meta-analyses involving more than 200,000 patients.[91,92] First-generation antihistamines are not recommended during breast-feeding because they are thought to inhibit lactation.[12-14] In addition, serious adverse CNS effects, including seizures, have been reported to develop in neonates receiving antihistamines, especially when they are premature.[12,13]

The newer generation antihistamines, such as cetirizine and loratadine, also appear safe during pregnancy.[13,14,92,93] They may be acceptable alternatives for severe allergies if the first-generation antihistamines are not tolerated.[13,14,92,93] These drugs are excreted into human milk, but in the case of loratadine, very small amounts reach the neonate.[13,14] The AAP classifies these drugs as compatible with breast-feeding.[12,13]

Asthma Medications

Pregnant women with asthma are at risk for neonatal death, preterm birth, low-birth-weight infants, preeclampsia, and small-for-gestational-age infants.[94] Asthmatic mothers may also have a higher rate of chorioamnionitis, hypertensive disorders of pregnancy, cesarean section, and prolonged hospital stay compared with control mothers.[94] Better asthma control has been associated with an improved outcome.[94]

Beta-adrenergic medications such as albuterol, metaproterenol, and terbutaline are commonly used in the treatment of asthma. Beta-adrenergic agents have also been used during the last trimester to treat premature labor.[13,14] Albuterol is the most commonly prescribed and is the treatment of choice in asthma.* It appears safe even when it is used long term.[13,14,92,94] None of the beta-adrenergic medications has been linked to fetal or congenital malformations, but some have been associated with significant cardiovascular and metabolic effects, which are transient and generally well tolerated by the fetus.* Transient hyperglycemia followed by insulin secretion may also occur, resulting in neonatal hypoglycemia, especially in diabetic patients.* Terbutaline, when it is used intravenously or orally in pregnant women, may result in significant maternal and fetal arrhythmias.[13,14] Maternal pulmonary edema and death have been reported.[13,14] The FDA has recommended a label change to add a warning against its use in preterm labor because safer beta$_2$-agonists and tocolytic agents are available.[95] Long-acting beta-agonists also appear to be safe during pregnancy.[13,14,92,94] Albuterol is compatible with breast-feeding.[12-14]

Ipratropium has not been found to be teratogenic in numerous animal models,[13,14,92,94] but there are few data regarding its safety in human pregnancy.[13,14] It is considered compatible with breast-feeding.[12,13]

*References 13, 14, 31, 92, 94.

Cromolyn sodium has not been associated with any significant risk of birth defects or negative perinatal outcomes.[13,14] It is considered compatible with breast-feeding.[12,13]

Corticosteroids

Corticosteroids are commonly used during pregnancy for the treatment of various disorders, including autoimmune diseases and asthma. Inhaled corticosteroids are the main therapy for the prevention of asthma exacerbations during pregnancy. Oral corticosteroids are the mainstay of therapy for acute exacerbations of asthma. Although they are not considered human teratogens, there may be a slightly increased incidence of orofacial clefts when oral steroids are used during the first trimester.* Furthermore, their use in the third trimester has been linked to an increased incidence of preterm delivery, low birth weight, preeclampsia, and cataracts in the newborn.† Other authors have also raised concerns about the development of congenital adrenal hyperplasia in newborns.[13,14] Prednisone is considered safe during breast-feeding.[12,13]

Data on the use of leukotriene antagonists in pregnancy are limited. One study did not find an association with congenital abnormalities, but there was a slight increase in intrauterine growth restriction. However, these results should be interpreted with caution because of the small sample size of the study.[13,14,98] Zileuton is mutagenic in animal studies and should be avoided during pregnancy and lactation.[13,14,98]

Decongestants

Decongestants with strong vasoconstrictive properties, such as phenylpropanolamine and pseudoephedrine, cause placental vasoconstriction and are not recommended during pregnancy.[13,14] There are limited data suggesting that their use in the first trimester may result in an increased incidence of abnormalities typically associated with placental vascular disruption, such as gastroschisis and intestinal atresia.[13,14] The risk, however, appears to be low. Pseudoephedrine is excreted in milk in small quantities, limiting the nursing infant's exposure.[13,14] The AAP classifies pseudoephedrine compatible with breast-feeding.[12,13]

KEY CONCEPTS

- Chemically induced birth defects are believed to be responsible for approximately 1 to 3% of anomalous births.
- The age of the fetus is crucial in determination of the impact of any given exposure. During the time of organogenesis (days 21-56 of fetal life) when major body organs are formed, exposure to a teratogen may result in major anatomic defects.
- Certain medications, such as anticonvulsants, warfarin derivatives, NSAIDs, sulfonamides, fluoroquinolones, ACE inhibitors, and oral hypoglycemic agents, are known teratogens or cause potential toxic effects in the newborn and should be avoided, if possible, during pregnancy.

Chapter 181

Labor and Delivery and Their Complications

Shoma Desai and Sean O. Henderson

PERSPECTIVE

Emergency department (ED) births are rare. In most cases, patients in labor are triaged directly to the obstetric suite for urgent management, maintaining a continuum of care with their primary providers. Because some births are precipitous and obstetric resources may not be immediately available, the emergency physician must possess the basic skills for intrapartum management of both normal and abnormal deliveries. In addition, a general knowledge of postpartum care is required in case of the occasional out-of-hospital delivery.[1,2]

Limitations of the Emergency Department

The ED is a suboptimal location for the management of a complicated delivery. The obstetric suite has experienced personnel and appropriate resources, including tocodynamometry, fetal scalp electrodes, intrauterine pressure monitors, vacuum extractors, and forceps. Also, the obstetrician usually has prenatal care information for each patient that helps optimize maternal and fetal outcomes. Such information includes accurate gestational dates, presence of multiple gestations, estimated fetal weights, detailed maternal pelvimetry, placental anatomy, amniocentesis results, maternal blood type and Rh factor, and prior documented obstetric complications. This information allows the obstetrician to anticipate complications of labor and delivery. It is difficult if not impossible to obtain these data in the ED while preparing for imminent delivery. Finally, in certain situations, cesarean section is the best way to ensure successful delivery. This surgical option is not available in the ED except in dire perimortem circumstances.

Epidemiology of Emergency Delivery

In 2004 the perinatal mortality rate in the United States was 6.2 per 1000 live births and fetal deaths (<20 weeks of gestation).[3] Delivery complications and mortalities do occur with greater frequency in the ED, where the perinatal mortality rate is approximately 8 to 10%.[4] There are multiple causes of the "high-risk" ED delivery profile. The ED is often selected by an obstetric population with unexpected complications. Antepartum hemorrhage, premature rupture of membranes (PROM), eclampsia, premature labor, abruptio placentae, precipitous delivery, malpresentation, and umbilical cord emergencies are overrepresented in the ED population.[4]

Psychosocial factors further skew the epidemiology of ED deliveries. Women who present with precipitous deliveries often have had little or no prenatal care.[5] Pregnant women who have drug or alcohol problems or are victims of domestic violence represent a disproportionate number of patients who deliver in the ED. Women who are unaware or in denial of their pregnancies or immigrants without access to other medical care also present to the ED when labor begins.[6-8]

Patient Transfer Considerations

Because of the high risk associated with ED delivery, patients should be transported to a facility that has obstetric and neonatal resources whenever possible. The management of a premature infant may require highly specialized intensive care that is unavailable at many community hospitals. The desire to transfer a woman with an impending high-risk delivery to such a facility should be tempered, however, by clinical and medicolegal judgment.[9,10]

Medicolegal Considerations

Transfer, with resultant en route delivery, can be disastrous for the mother and fetus. Such a transfer also violates federal law. The Consolidated Omnibus Reconciliation Budget Act (COBRA) of 1989 was based on an "inappropriate" obstetric transfer.[11] Federal law has identified labor as a condition unsuitable for transfer because of its unstable nature. Although the intent of this legislation is to protect women from medical abandonment because of financial reasons, COBRA runs the risk of forcing emergency physicians to occasionally perform difficult high-risk deliveries that might have better outcomes with transfer.[12]

Nursery Requirements

For many ED deliveries, labor will have progressed to a point at which tocolysis is contraindicated and delivery is imminent. In general, this is when the mother feels the urge to push or the head is crowning. Whenever possible, a neonatologist or pediatrician should attend high-risk preterm (<36 weeks of gestation) deliveries, and preparations for neonatal resuscitation and high-level nursery care should be initiated (Box 181-1).

NORMAL DELIVERY

Although the epidemiology and high complication rate associated with ED births demand caution, most are normal deliveries. Knowledge of normal labor and delivery mechanics aids safe vaginal delivery and facilitates the identification of complications.

Whenever a woman in the third trimester of pregnancy seeks treatment in the ED, the possibility that she is in labor must be considered. A wide array of nonspecific symptoms may herald the onset of labor. Abdominal pain, back pain, cramping, nausea,

www.ketabpezeshki.com 66485457-66963820

vomiting, urinary urgency, stress incontinence, and anxiety can be symptoms of labor. After 24 weeks' gestation, any medical assessment should include the mother and the fetus because fetal viability becomes established near that time. In addition, given the generally high-risk nature of this population of patients and the abundance of body fluids that the health care provider and newborn are exposed to during delivery, serologic testing for infectious disease may be warranted. With the development of rapid bedside testing technology, human immunodeficiency virus (HIV) infection and hepatitis screening before delivery is indicated in a significant group of patients presenting with active labor.

Distinguishing False from True Labor

Braxton Hicks contractions, or false labor, must be differentiated from true labor. During the third trimester, the uterus develops into a contractile organ. After 30 weeks of gestation, the previously small and uncoordinated contractions of the uterus become more synchronous and may be perceived by the mother. Braxton Hicks contractions do not escalate in frequency or duration, in contrast to the contractions of true labor. By definition, this muscle activity is associated with minimal or no cervical dilation or effacement. Examination should also reveal intact membranes. Care not to rupture the membranes is important to avoid inducing labor prematurely. If the diagnosis remains in doubt, external electrical monitoring of uterine activity can rule out true labor. Any discomfort associated with false labor is usually relieved with mild analgesia, ambulation, or change in activity.

Unlike false labor, true labor is characterized by cyclic uterine contractions of increasing frequency, duration, and strength, culminating in delivery of the fetus and placenta. In contrast to Braxton Hicks contractions, true labor causes cervical dilation to begin, marking the first stage of labor.

Box 181-1 Levels of Nursery Care

Level 1 Nurseries
These nurseries care for infants presumed healthy. In such units, screening and surveillance are primary responsibilities. Rooming-in units are encouraged, with emphasis on support of breast-feeding and assessment of parenting skills.

Level 2 Nurseries
These nurseries care for infants >30 weeks' gestation and >1200 g who require special attention short of circulatory or ventilator support and major surgical procedures. A high percentage of the patients in such nurseries have had obstetric complications (e.g., birth trauma, fetal distress, and obstetric anesthesia).

Level 3 Nurseries
These nurseries are staffed and equipped to care for all newborn infants who are critically ill, regardless of the level of support required. They are regional institutions serving as referral centers for other nurseries and for this reason are often linked with transport services.

Perinatal Centers
A perinatal center provides services to high-risk mothers and to infants requiring level 3 nursery care. Ample data show a higher neonatal survival rate for high-risk pregnancies cared for in such centers.

Bloody Show

Early in pregnancy, the cervix becomes increasingly vascular and develops edema, giving the cervix a boggy texture. The vascularity of the cervix also increases, giving rise to Chadwick's sign (a blue-violet coloration). At the onset of labor, the cervical mucus plug is expelled, resulting in what is called a bloody show. The bleeding associated with the process is slight, and usually only a few dark red spots are noticed. The dark color is due to its venous origin, and it is admixed with the mucous components of the cervical plug. The significance of a bloody show is that it is a fairly reliable indicator of the onset of true labor, specifically stage 1. Bloody show is not a contraindication to vaginal examination for determination of cervical effacement and dilation. If bleeding continues or is of a larger volume, more serious causes should be suspected, such as placenta previa and placental abruption, which are contraindications for a vaginal examination.

Stages of Labor

First Stage of Labor

The first stage of labor is the cervical stage, ending with a completely dilated, fully effaced cervix. It is divided into a latent phase, with slow cervical dilation, and an active phase, with more rapid dilation. The active phase begins once the cervix is dilated 3 cm.[13] In multiparous women, the active phase can progress rapidly into stage 2 of labor (delivery of the fetus). Most women who deliver in the ED arrive while in the active phase of stage 1 or early stage 2 labor (Fig. 181-1).[4]

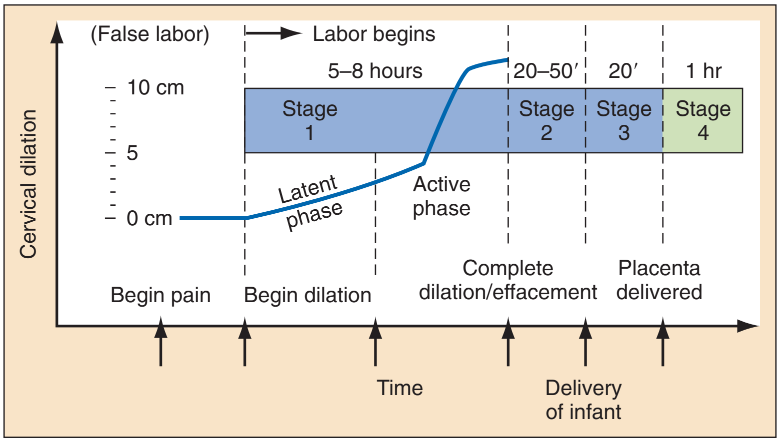

Figure 181-1. Stages of labor and delivery. Stage 1, cervical stage; stage 2, fetal expulsion; stage 3, placental expulsion (20 minutes); stage 4, uterine contraction (1 hour post partum).

www.ketabpezeshki.com 66485457-66963820

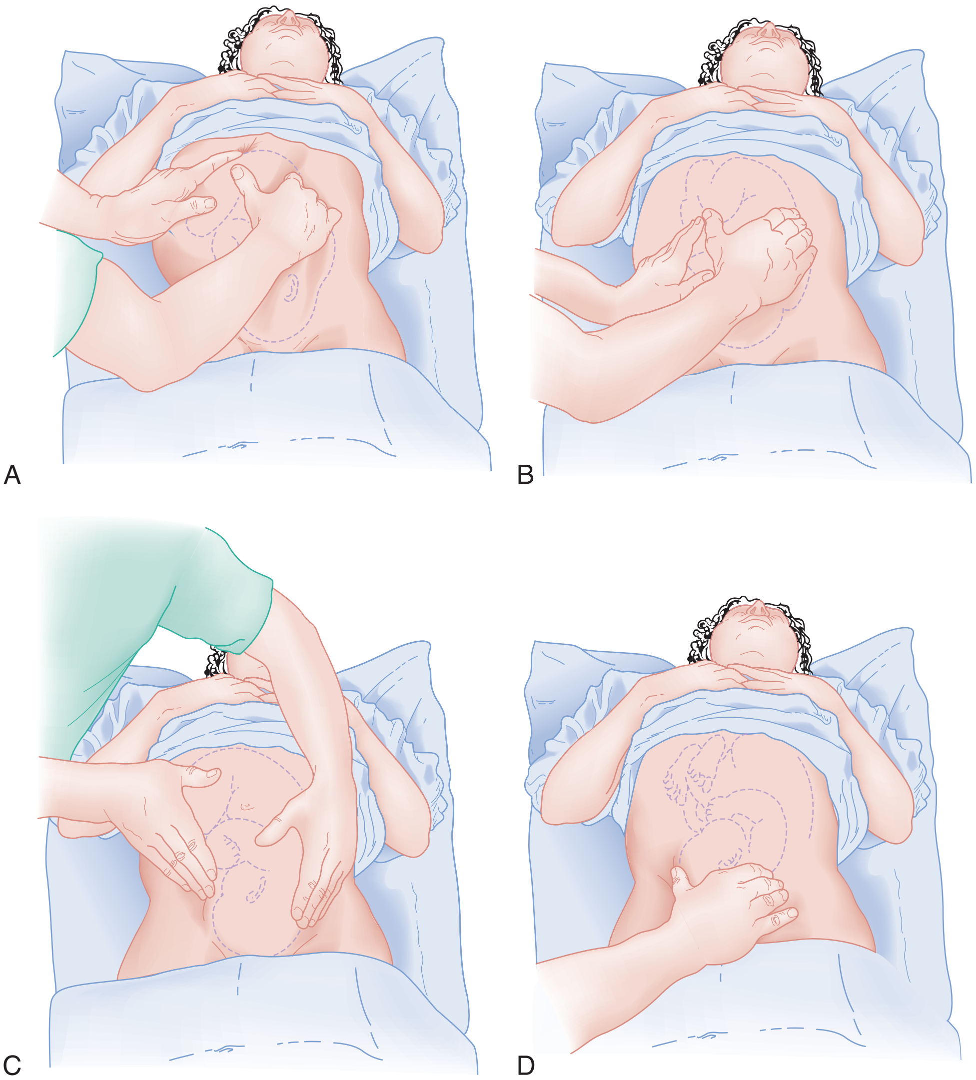

Figure 181-2. Leopold's maneuvers. **A,** The first Leopold maneuver reveals what fetal part occupies the fundus. **B,** The second Leopold maneuver reveals the position of the fetal back. **C,** The third Leopold maneuver reveals what fetal part lies over the pelvic inlet. **D,** The fourth Leopold maneuver reveals the position of the cephalic prominence. (Modified from Willson JR, et al: Obstetrics and Gynecology, 9th ed. St. Louis, Mosby, 1991.)

The duration of the first stage of labor averages 8 hours in nulliparous women and 5 hours in multiparous women. During this time, frequent assessment of fetal well-being is important. For low-risk pregnancies, fetal heart tones should be auscultated approximately every 15 minutes. For higher risk pregnancies, continuous external electrical monitoring may help identify fetal distress, allowing appropriate intervention.[14]

Abdominal examination with Leopold's maneuvers may confirm the lie of the fetus (Fig. 181-2). After labor has begun, particularly during the active phase of stage 1, Leopold's maneuvers are difficult to use. The firm contractions of the uterus prevent the identification of fetal "small parts." Other modalities of assessing the lie, such as ultrasonography, may be necessary if presentation remains in question.[15]

Maternal examination also provides a rough guide to gestational age. At 20 weeks' gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the fetus "drops" into the pelvis (Fig. 181-3). These estimates help establish gestational age rapidly.

The accurate determination of the stage of labor depends on examination of the cervix. A sterile approach with use of sterile gloves, a sterile speculum, and povidone-iodine (Betadine) solution is indicated to prevent ascending infection, such as chorioamnionitis. On pelvic examination, the clinician should determine the following:

Effacement refers to the thickness of the cervix. A paper-thin cervix is 100% effaced.

Dilation indicates the diameter of the cervical opening in centimeters. Complete, or maximum, dilation is 10 cm.

Position describes the relationship of the fetal presenting part to the birth canal. The most common position of the head is occiput anterior.

Station indicates the relationship of the presenting fetal part to the maternal ischial spines (Fig. 181-4).

Presentation specifies the anatomic part of the fetus leading through the birth canal.

In 95% of all labors, the presenting part is the occiput, or vertex. On digital examination, a smooth surface with 360 degrees of firm bony contours and palpable suture lines is noted. Palpation of the suture lines and the fontanels where they join allows the examiner to determine the direction the fetus is facing. Three sutures radiate from the posterior fontanel, and four radiate from the anterior fontanel (Fig. 181-5). The lateral margins are examined carefully

for fingers or facial parts that indicate compound or brow presentations.

When the clinician suspects rupture of membranes, a sterile speculum examination is performed. This may reveal pooling of amniotic fluid. Two tests to confirm the presence of amniotic fluid include a fernlike pattern when the fluid is allowed to dry on a microscope slide and the use of Nitrazine paper, which should turn blue, indicating an alkaline amniotic fluid ($pH > 6$). Although vaginal blood, cervical mucus, semen, and infection can interfere

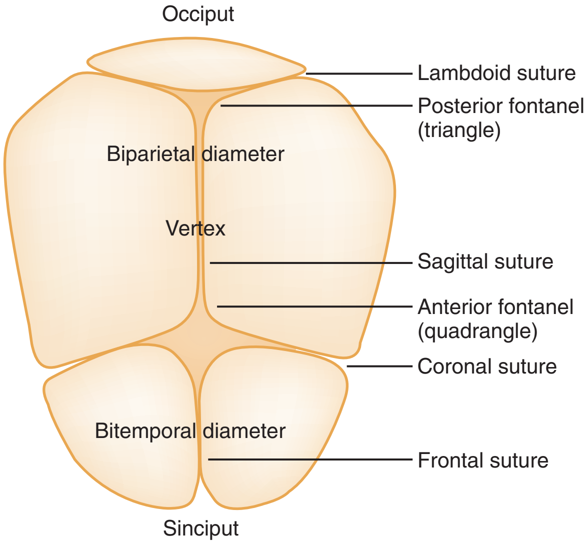

Figure 181-5. Bone landmarks of the fetal skull. (Modified from Willson JR, et al: Obstetrics and Gynecology, 9th ed. St. Louis, Mosby, 1991.)

with results, sensitivities of both Nitrazine paper and ferning in detection of amniotic fluid are nearly 90%.[16]

Of note, if vaginal bleeding is evident, both digital and speculum examination of the pelvis should be deferred until an ultrasound study can be obtained to rule out placenta previa.

Second Stage of Labor

The second stage of labor is characterized by a fully dilated cervix and accompanied by the urge to bear down and push with each uterine contraction. The fetal station is advanced to +3, with crowning of the presenting part as expulsion begins. Stage 2 uterine contractions may last 1 or 2 minutes and recur after a resting phase of less than 1 minute. The median duration of this stage is 50 minutes in nulliparous women and 20 minutes in multiparous women. More rapid progression through stage 2 should be anticipated for low-birth-weight premature infants. A prolonged second stage of labor is defined as more than 3 hours in nulliparous women if regional anesthesia is administered, more than 2 hours in nulliparous women without anesthesia or in multiparous women with regional anesthesia, and more than 1 hour in multiparous women without regional anesthesia.[17] Prolonged second stage of labor is associated with an increase in maternal complications, including postpartum hemorrhage, infection, and severe vaginal lacerations.[18]

Antenatal Fetal Assessment

The assessment of a woman in the third trimester includes an assessment of fetal well-being. After 24 weeks' gestation, the fetal condition affects clinical decision-making. During labor and delivery, the identification of fetal distress and appropriate intervention can reduce fetal morbidity and mortality.

There are currently three methods of assessing a fetus in utero. Clinical monitoring, electrical monitoring, and ultrasonography all have a role in the assessment of the fetus. External electrical monitoring and ultrasonography merit consideration for use in the care of women laboring in the ED. The machinery for both technologies is portable and easy to use and can provide real-time information helpful for diagnosis of fetal distress and assistance with intrapartum decision-making.

Electronic Fetal Monitoring. Intrapartum fetal assessment by electronic fetal monitoring is most useful during stage 1 of labor.

www.ketabpezeshki.com 66485457-66963820

Electronic fetal monitoring confirms true labor and may help diagnose fetal distress. Tracings of fetal heart rate and uterine activity provide information that in combination with clinical data can presage fetal distress due to hypoxia and provide a window for intervention.

Uterine activity is measured transabdominally by a pressure transducer, creating a recording of the contraction frequency. Because the measurements are indirect, the strength of the contractions correlates poorly with the tracing. The tracings are position and placement sensitive. Documentation of organized cyclic uterine contractions confirms the onset of labor and rules out Braxton Hicks contractions that are too disorganized to be registered in this manner. Premature onset of labor can also be diagnosed. Finally, this type of external electrical monitoring may be used to determine the efficacy of administered tocolytic agents.

Fetal heart rate tracings have several components that can be assessed: baseline heart rate, variability, accelerations, decelerations, and diagnostic patterns. Baseline heart rate, by definition, is the average fetal heart rate during a 10-minute period (in the absence of a uterine contraction) and is the most important aspect of fetal heart rate monitoring. Fetal bradycardia is defined as a baseline rate of less than 110 beats per minute; fetal tachycardia is defined as a baseline rate of more than 160 beats per minute.[19]

Variability can be instantaneous (beat to beat) or long term during intervals of 1 minute or more. Both types of variability are indicators of fetal well-being. Accelerations of heart rate are an important component of long-term variability. Accelerations occur during fetal movement and reflect an alert, mobile fetus. Brief periods of umbilical cord compression also can cause accelerations by decreasing the venous return and reflexively generating fetal tachycardia. Meanwhile, decreased variability may indicate fetal acidemia and hypoxemia or may be a side effect of a wide array of drugs. Analgesics, sedative-hypnotics, phenothiazines, and alcohol have been reported to cause decreased variability.

Decelerations in fetal heart rate are more complicated, and their interpretation should be integrated with the clinical situation. There are three types of deceleration: variable, early, and late (Fig. 181-6). These terms refer to the timing of the deceleration relative to the uterine contraction.

Variable and early decelerations are common. Present on more than 50% of all tracings, these heart rate changes can represent physiologic reflexes associated with head compression in the birth canal or intermittent cord compression. Variable decelerations that are persistent and repetitive usually indicate repeated episodes of umbilical cord compression. The resultant hypoxia and acidosis may cause fetal distress. Attempts to shift maternal and fetal weight off the umbilical cord by changing position are indicated. If these variable decelerations continue, the situation calls for efforts to hasten the delivery or, if obstetric backup becomes available, to perform an emergency cesarean section.

Late decelerations are more serious and most often indicate uteroplacental insufficiency. The tracing contours are generally smooth, with the heart rate nadir occurring well after maximal uterine contraction (typically 30 seconds or more afterward).[19] The lag, slope, and magnitude of late decelerations correlate with increasing fetal hypoxia. Late decelerations are particularly ominous in association with poor variability, nonreactivity, and baseline bradycardia. When these findings are present, immediate obstetric consultation for delivery to prevent further hypoxia is indicated. The need for newborn resuscitation should be anticipated and preparation for critical care established for these deliveries. Overall, 30% of infants with late decelerations have good outcomes. The remaining 70% have suboptimal outcomes related to either the underlying pathologic condition or hypoxia.

Finally, the clinician should be aware of the significance of sinusoidal tracings. Tracings of this type have low baseline heart rates and little beat-to-beat variability. The sinusoidal tracing is an ominous finding that is often premorbid. The differential diagnosis includes erythroblastosis fetalis, placental abruption, fetal hemorrhage (trauma), and amnionitis.

Ultrasonography. Ultrasonographic techniques have wide application in obstetric care. In the third trimester or during labor, ultrasonography can provide crucial information pertaining to impending delivery. When a technician and radiologist are available, the gestational age, biophysical profile, and amniotic fluid index as well as a survey of fetal and placental anatomy may be discerned (Table 181-1). The parameters of immediate interest in the ED are fetal viability (specifically in utero gestation and fetal heart rate), lie, and presentation. Ultrasonography may also reveal multiple gestations, allowing preparation and early communication with other specialists (from obstetrics, neonatology, and anesthesia). In 1991 the American College of Obstetricians and Gynecologists (ACOG) published recommendations regarding the indications for ultrasonography in the third trimester (Box 181-2). A 2- to 5-MHz transducer is appropriate for all bedside transabdominal sonographic assessments. Transvaginal ultrasonography is relatively contraindicated in the peripartum period, particularly in the cases of PROM and placenta previa.[20]

Delivery

As stage 2 of labor progresses, preparation for delivery should be under way. A radiant warmer should be available and heated. Neonatal resuscitation adjuncts, such as a towel, scissors, umbilical clamps, bulb suction, airway management equipment (oxygen, bag-mask device with appropriate-sized masks, and endotracheal intubation and suctioning equipment for meconium), and equipment to achieve vascular access, should be available. Most deliveries require only basic equipment to cut and clamp the umbilical cord, to suction the mouth and nose, and to dry and stimulate the infant. A nurse should be at the bedside to coach and to provide reassurance to the mother.

The mother is placed in the dorsal lithotomy position and prepared for delivery. The Sims position, or left lateral position with knees drawn toward the mother's chest and back to the physician, is also an acceptable position for delivery. The vulva and perineum are cleared and gently scrubbed with sterile water or saline, directing all mucoid debris and feces away from the introitus. A repeated sterile examination to assess labor progression and to confirm presentation may be performed. Firm digital stretching of the perineum, particularly posteriorly, may prevent tears and lacerations later in delivery.

Controlled, coordinated expulsion with coaching to sustain each push aids with crowning and delivery of the head. When the fetus is crowning, care is exercised to have the delivery occur in a slow, controlled manner. Precipitous delivery is more likely to cause maternal injuries, such as perineal, rectal, urethral, labial, vaginal, and uterine lacerations, and fetal injuries.[21]

The most vulnerable moment is when the fetal head begins to stretch and distend the perineum. Instructing the mother to pant and not push slows the passage of the head and the shoulders as indicated. Calm communication between the physician and the mother is the best way to maintain control of the delivery. With a controlled delivery, routine performance of an episiotomy is not recommended.

One described technique to potentially decrease the rate of maternal injury is the modified Ritgen maneuver.[22] In the modified Ritgen maneuver, a towel-draped, gloved hand is used to stretch the perineum and gently exert pressure on the chin of the fetus. The second hand puts pressure on the occiput superiorly, guiding the head into slight extension. When the head is at the perineum, this slight extension of the head promotes delivery by positioning the head so that its smallest diameter passes through the pelvic outlet and perineum.

Table 181-1 Biophysical Profile: 30 Minutes of Ultrasonographic Observation

ELEMENT ASSESSED	NORMAL SCORE = 2	ABNORMAL SCORE = 0
Fetal heart rate reactivity	2 accelerations >15 beats/minute for >15 seconds	<2 accelerations
Amniotic fluid index	1 pocket >1 cm in orthogonal planes	No large pockets
Fetal muscle tone	1 episode of active flexion-extension with full return to flexed posture	<1 episode or slow, incomplete actions
Body movements	3 discrete moves	≤2
Breathing motions	1 episode of fetal breathing of at least 60 seconds in duration during 30 minutes of observation	No breathing activity *or* The absence of 1 episode of fetal breathing of at least 60 seconds in duration during 30 minutes of observation

Box 181-2 Third-Trimester Ultrasonography: Possible Indications

Determine number of fetuses
Establish fetal presentation
Identify fetal heart motion
Locate placenta
Measure amniotic fluid
Determine gestational age
Survey fetal anatomy
Diagnose cord prolapse
Diagnose cause of third-trimester bleeding
Rule out placental abruption

After the head is delivered, the physician allows the head to rotate toward the maternal thigh and clears the fetal face and airway. Coordination with the mother is important to prevent uncontrolled fetal expulsion.

Next, the shoulders, usually anterior shoulder first, clear the perineum. The shoulders often deliver spontaneously, with little effort by the physician. First, gentle downward traction on the head promotes delivery of the anterior shoulder. A subsequent upward motion pulls the posterior shoulder through the pelvic outlet, minimizing maternal trauma. If delay occurs in delivery of the shoulders, the potential for shoulder dystocia should be considered.

As the infant clears the perineum, attention focuses on the umbilical cord. The infant should be kept low or at the level of the perineum to promote blood flow into the infant from the placenta. The cord is clamped and cut. Clamps should be placed 4 or 5 cm apart, with the proximal clamp 10 cm from the infant's abdomen. An adequate umbilical stump is important for venous access if the child requires resuscitation. Suctioning of the nose and mouth at this time may reduce secretions that can cause increased airway resistance.

The infant is now clear of the mother and can be wrapped in towels and moved to the warmer. Gentle drying with a towel and suctioning usually provide adequate respiratory stimulation. If not, flicking the soles of the feet and rubbing the back are other modalities. Apgar scores at 1, 5, and 10 minutes after birth should be documented.

Episiotomy. Previously, the need for episiotomy in normal deliveries was an area of controversy. The original potential benefit of episiotomy included the substitution of a straight surgical incision for a ragged, uncontrolled traumatic laceration. Theoretically, the surgical approach decreased the incidence of severe rectovaginal tears. This rationale led to widespread routine episiotomy, with a medial incision used in the United States and a mediolateral incision used in the Commonwealth countries.

Recent literature has shown that both types of incisions increase maternal morbidity, and they are no longer recommended for uncomplicated deliveries. Women receiving episiotomies have been shown to have a higher incidence of perineal trauma and maternal blood loss during delivery and more pelvic pain, sexual dysfunction, and urinary incontinence in the postpartum period.[23]

Episiotomy should be performed only for specific indications, such as shoulder dystocia or breech delivery. When the decision is made to use an episiotomy, the procedure should be done before excessive stretching of the perineal muscles occurs but near the time of delivery to avoid excessive bleeding. Common practice is to cut the episiotomy when the head is visible during a contraction and the introitus opens to a diameter of 3 or 4 cm. Most authors currently recommend a mediolateral incision to avoid perineal tears and rectal involvement; this is particularly true for a complicated delivery in which lacerations extending the surgical incision are likely (Fig. 181-7).

Table 181-2 summarizes some of the adjuncts used in normal labor and delivery, with recommendations for their use in the high-risk setting of an ED delivery.

Third Stage of Labor

The third stage of labor involves the delivery of the placenta and is a time of observation of the patient with frequent checks of the tone and height of the uterine fundus. Signs of placental separation include the following:

The uterus becomes firmer and rises.
The umbilical cord lengthens 5 to 10 cm.
There is a sudden gush of blood.[24]

These signs usually occur within 5 to 10 minutes of the delivery of the infant but may extend to 30 minutes. The risk of postpartum hemorrhage increases beyond 18 minutes and is in fact up to six times more likely after 30 minutes.[25] Although the placenta may be delivered expectantly, active management reduces the length of the third stage of labor and thereby decreases the risk of postpartum hemorrhage. Active management includes the administration of uterotonics, gentle traction of the clamped umbilical cord with mild pressure applied above the symphysis pubis, and uterine massage after delivery.[26] Be aware that any attempt to deliver the placenta before it separates is contraindicated.

Examination of the placenta and umbilical cord is an essential part of the delivery process. Abnormalities of the cord should be noted at this time. Also, a segment of the umbilical cord should be kept available as a source of cord blood.

Normally a three-vessel structure, the umbilical cord is filled with a connective tissue known as Wharton's jelly and is approximately 50 to 60 cm long and 12 mm in diameter. Normal architecture places the two umbilical arteries on either side of the single umbilical vein. A two-vessel cord (one umbilical artery) occurs in 1 of 500 deliveries, is more common in African Americans, and is a result of aplasia or atrophy. Approximately 30% of two-vessel cord infants have congenital defects. An association also exists between fetal structural anomalies and placental vascular occlusion or thrombosis.[27]

The placenta should also be examined for abnormalities. Clots adherent to the uterine aspect may indicate placental abruption. Accessory lobes (succenturiate placenta if completely separate) and abnormal cord insertion are common abnormalities. The umbilical cord and placenta routinely should be held for pathologic review.[28] The discovery of an incomplete placenta or

Table 181-2 Risk-Benefit Analysis of Routine Adjuncts to Normal Labor and Delivery

PRACTICE OR PROCEDURE	RISK	BENEFIT	UTILITY IN THE EMERGENCY DEPARTMENT
Nothing by mouth status and intravenous hydration	Fluid overload, osmolar and acid-base disturbances	Venous access, decreased risk of aspiration	Yes
Enemas	Time-consuming	Reduced pain caused by constipation	Minimal or none
Pubic shaving	Infections and irritation	None	None
Nitrous oxide analgesia	Incomplete pain control	Self-administered, minimal fetal side effects, noninvasive	Yes
Narcotic analgesia	Neonatal depression	Excellent pain control	As needed
Regional anesthesia	Technically difficult, incomplete pain control	Excellent pain control when technically successful (paracervical or pudendal block)	Variable (operator dependent)
Electronic fetal monitoring	Increased incidence of surgical intervention	Early diagnosis of fetal distress	Variable (operator dependent)
Ultrasonography	None	Rapid augmentation of database	Yes (operator dependent)
Amniotomy	Augmented labor, prolapsed umbilical cord	None	No
Episiotomy	Poor maternal outcomes	None for uncomplicated delivery	No
Ritgen maneuver	None	Decreased birth trauma	Yes

membranes should alert the emergency physician to the possibility of postpartum complications and should be documented.

Fourth Stage of Labor

The fourth stage of labor refers to the first hour after delivery of the placenta and is a critical period because postpartum hemorrhage is most likely to occur during this time. Thus careful examination and repair of any vaginal lacerations should be performed. The cervix and vaginal fornices are visually inspected to avoid missing deep lacerations as a result of delivery.

At this point, oxytocin is infused to promote contraction of the uterus and to control hemorrhage. The uterus is evaluated frequently for tone and massaged transabdominally if any sign of relaxation exists. Oxytocin should not be given before delivery of the placenta because this may result in the trapping of placental fragments or may hinder the delivery of an undetected twin.

SPECIFIC DISORDERS

Third-Trimester Complications Associated with Delivery

Obstetric problems in the third trimester often result in the initiation of labor. Premature labor, PROM, and third-trimester bleeding are relatively common complications. The fundamental

question to be addressed in these settings is whether the fetus would fare better in utero or delivered.

Premature Labor

Perspective. Premature or preterm labor and fetal immaturity are the leading causes of neonatal mortality. Preterm labor is defined as uterine contractions with cervical changes before 37 weeks of gestation. Women with premature labor are a heterogeneous group. Many underlying conditions result in preterm labor, which accounts for 9.6% of all pregnancies but 70% of all perinatal mortality.[29] Factors linked to this problem include substance abuse, history of preterm delivery, multiple gestations, placental anomalies, infections, and lifestyle or psychosocial stressors[30] (Box 181-3). The unexpected nature of premature labor often results in an ED visit. When delivery is not imminent, the patient can be moved to the obstetrics unit for further care.

Clinical Features. The diagnosis of preterm labor requires the identification of uterine activity and cervical changes before 37 weeks of gestation. Early maternal signs and symptoms include an increase or change in vaginal discharge, pain resulting from uterine contractions (sometimes perceived as low back pain), pelvic pressure, vaginal bleeding (usually bloody show), and fluid leak.

Diagnostic Strategies. If uterine contractions and cervical changes are present and the estimated fetal weight on ultrasonography is less than 2500 g, the diagnosis of premature labor is likely. The differentiation of false labor (Braxton Hicks contractions) from true labor is best done by electrical monitoring. Ultrasonography may aid in the diagnosis because fetal breathing movements make the diagnosis of false labor unlikely. The initial evaluation of a woman with possible preterm labor includes urinalysis, complete blood count, and pelvic ultrasonography. If delivery is not imminent, these studies can be performed in the ED or obstetrics area, whichever would provide the best monitoring. When possible, these patients should be transferred to a perinatal center with an associated intensive care unit.

Management. A viable fetus and healthy mother are indications for medical management directed toward the prolongation of gestation. Preterm labor should not be postponed with medical management in the cases of fetal compromise, major congenital anomalies, intrauterine infection, placental abruption, eclampsia, significant cervical dilation, or, most important, PROM.[31]

The treatment of preterm labor involves multiple modalities. Tocolytics and fetal maturation therapy combined with bed rest and hydration are used in the hope of prolonging pregnancy (Box 181-4). These patients optimally should be transferred to an appropriate center before delivery whenever possible because medical management fails in more than 25% of preterm patients in whom it is attempted.[32]

Tocolysis

The two classically used tocolytics are magnesium sulfate and beta-mimetic drugs. Other medications that have been shown to be effective include prostaglandin synthetase inhibitors (nonsteroidal anti-inflammatory drugs [NSAIDs]) and calcium channel blockers.[33] When they are indicated and in coordination with an obstetric consultant, tocolytics initiated in the ED may arrest premature labor, preventing imminent delivery in 75 to 80% of patients for 48 to 72 hours.[29]

Magnesium Sulfate

Magnesium sulfate competitively inhibits calcium uptake into smooth muscle and allows relaxation. The efficacy of magnesium sulfate as a tocolytic agent has not been clearly established.[34] Women treated with magnesium require monitoring. Magnesium produces respiratory and neurologic depression at elevated levels, exacerbated by renal insufficiency. Pulmonary edema and cardiac dysrhythmias have also been reported.[29] These effects can be reversed rapidly by the administration of calcium-containing solutions (i.e., 1 g of 10% calcium gluconate solution) (Table 181-3).

Beta-Mimetics

Beta-mimetics (ritodrine and terbutaline) cause smooth muscle relaxation by activating enzymes that bind calcium to the sarcoplasmic reticulum. This effect is mediated by $beta_2$ receptors that increase cyclic adenosine monophosphate concentrations in the myometrium. The beta-mimetic is titrated to effect because the dosage needed to eliminate uterine activity varies. In one meta-analysis, beta-mimetics and magnesium sulfate had similar efficacy in elimination of contractions.[33]

Despite evidence that beta-mimetics are effective tocolytics, their side effect profile is somewhat prohibitive for their selection

www.ketabpezeshki.com 66485457-66963820

Table 181-3 Drug and Labor Interactions

DRUG	EFFECT ON LABOR
Barbiturates	Can stop labor in anesthetic doses
Alcohol	Decreases oxytocin release, smooth muscle relaxant
Cocaine	Increased prematurity, placental infarction
Caffeine or aminophylline	Increased duration of labor
Narcotics	Increased latent phase, slow dilation (minimal effect once in active labor)
Atropine, scopolamine	Lower uterine segment relaxation, decreased frequency of contractions
Halothane	Strong inhibition of labor
IV nitroglycerin	Profound uterine relaxation

Box 181-5 Contraindications to Tocolysis

Absolute
Acute vaginal bleeding
Fetal distress (not tachycardia alone)
Lethal fetal anomaly
Chorioamnionitis
Preeclampsia or eclampsia
Sepsis
Disseminated intravascular coagulopathy

Relative
Chronic hypertension
Cardiopulmonary disease
Stable placenta previa
Cervical dilation >5 cm
Placental abruption

over other options. Maternal pulmonary edema, myocardial ischemia, and cardiac dysrhythmia are the main adverse effects of high-dose beta-mimetics. Pulmonary edema is more likely to occur in mothers with preexisting cardiac disease, multiple gestation, and maternal infection. Pulmonary edema is caused by high-output failure and tends to occur when there is sustained maternal tachycardia of more than 120 beats/minute. Beta-mimetics should be gradually titrated according to uterine activity and maternal heart rate.[30]

Other beta-mimetic side effects include gluconeogenesis and glycogenolysis, which can be a problem for diabetic mothers. Surveillance of the urine for glucose and ketones is recommended. Fetal heart stimulation can result in both fetal dysrhythmia and cardiac hypertrophy. Also, some studies have shown an association between beta-mimetics and an increased incidence of fetal intraventricular hemorrhage.[35]

NSAIDs

The prostaglandin synthetase inhibitors, specifically indomethacin and sulindac, have been shown to be as effective as magnesium and the beta-mimetics in multiple trials. However, in the fetus, pulmonary hypertension, ductus arteriosus constriction, renal insufficiency, necrotizing enterocolitis, and intraventricular hemorrhage have been reported with NSAID use. Potential maternal side effects include a prolonged bleeding time and renal insufficiency.[33,36]

Calcium Channel Blockers

Calcium channel blockers have also been used as tocolytics with success, reducing muscle contractility by their effect on transmembrane calcium influx. Nifedipine or nicardipine may be given.[37] Equal in efficacy to ritodrine and magnesium sulfate, calcium channel blockers have been shown to have relatively good maternal and fetal side effect profiles.[30]

Aggressive titratable tocolytics are best for the initial 24 to 48 hours of preterm labor. After uterine contractions have been stopped, the patient can usually be maintained with oral agents, although the benefits of maintenance tocolysis, studied to date primarily with beta-mimetics and magnesium, have yet to be shown.[33] It is important to review the contraindications to tocolytics before initiation of these therapies (Box 181-5). Any patient receiving tocolytics should be externally monitored (electrically) for signs of fetal distress.

Premature Rupture of Membranes

Clinical Features. PROM, also known as amniorrhexis, is defined as rupture of the amniotic and chorionic membranes before the onset of labor. It affects 3% of all gestations.[38] During pregnancy, the chorionic and amniotic membranes protect the fetus from infection and provide an environment that allows fetal growth and movement. The amniotic fluid is constantly exchanged by fetal swallowing and urination and umbilical cord transfer. The fetal airway also contains a secreted fluid that allows fetal breathing movements, promoting fetal respiratory development. This fluid is produced at 5 mL/kg/hr at term gestation and is resorbed rapidly by the pulmonary lymphatics, blood vessels, and upper airway at birth.

The word *premature* in PROM refers to rupture before labor, not to fetal prematurity. In 8% of PROM cases, the fetus is at or near term, and PROM may result in normal labor. When PROM occurs before 37 weeks, it is called preterm PROM and is associated with significant fetal morbidity and mortality. PROM is the inciting event in one third of all preterm deliveries.[39]

After the membranes rupture, the period from latency to the onset of labor varies. Longer latent periods are common earlier in pregnancy, and the latency shortens as gestational age increases. At term, labor is a desirable result of PROM, but with fetal immaturity labor is a problem because delivery would result in fetal complications, such as hyaline membrane disease.

Diagnostic Strategies. The diagnosis of PROM usually can be established by history and physical examination. The patient usually describes a spontaneous gush of watery fluid followed by a mild persistent seepage. In most cases, the patient suggests the diagnosis and usually is correct. Urinary incontinence or excess vaginal or cervical secretions are occasionally confused with PROM.

Examination of women with potential PROM is performed under sterile conditions to prevent ascending infection. Direct digital examination of the cervix is avoided. The incidence of infection has been shown to be proportional to the number of examinations. The identification of amniotic fluid was previously discussed. Table 181-4 summarizes the bedside testing modalities available to confirm the diagnosis of PROM. Visualization of the cervix for prolapsed cord or abnormal fetal presentation (prolapse of a small part) is performed during the evaluation for effacement and dilation. Culture specimens for group B streptococci, *Chlamydia trachomatis,* and *Neisseria gonorrhoeae* should be obtained.[39]

Management. When the diagnosis of PROM is established, management depends on several factors: the gestational age and fetal maturity, the presence of active labor, the presence or absence of infection, the presence of placental abruption, and the degree of fetal well-being or distress.[39] Fetal heart rate monitoring, obstetric consultation, and admission are indicated.

www.ketabpezeshki.com 66485457-66963820

Table 181-4 Bedside Testing for Premature Rupture of Membranes

METHOD	RESULT
Nitrazine	Amniotic fluid (pH >6.5) will turn nitrazine paper blue; normal vaginal secretions (pH <5.5) will leave nitrazine paper yellow
Ferning	Amniotic fluid crystallizes
Smear combustion	Amniotic fluid, when flamed, turns white and crystallizes Vaginal secretions caramelize and turn brown

Gestational age may be well known by menstrual history and previous ultrasonographic scans. In the absence of such data, immediate ultrasonography provides an estimated gestational age quickly. Fetal maturity is a more complex determination. Beyond 36 weeks of gestation, fetal pulmonary maturity is likely. If the gestational age is less than 36 weeks, testing of the amniotic fluid for the lecithin-to-sphingomyelin ratio or for phosphatidylglycerol can establish maturity. Fluid pooling in the posterior vaginal vault can be used for this purpose.

In the immature fetus (24-31 weeks of gestation), administration of corticosteroids can accelerate pulmonary maturation and, some studies suggest, also decrease rates of intraventricular hemorrhage and necrotizing enterocolitis.[40] The benefit of this strategy has been shown with preterm PROM; however, this therapy is less well documented for PROM. In PROM, treatment with steroids seems to decrease the incidence and severity of hyaline membrane disease but may increase the risk of maternal infectious complications. Rupture of the membranes also stimulates fetal lung maturation, making it more difficult to establish a treatment benefit in PROM compared with preterm PROM. Therefore, patients with PROM between 31 and 33 weeks' gestation are usually managed expectantly (unless fetal pulmonary maturity can be confirmed); those at or beyond 34 weeks of gestation are generally delivered.[40] When gestational age is less than 26 weeks, the latent interval to delivery is often 1 week. Tocolytics seem an obvious choice, but their use is controversial. When tocolytics are used, the goal is to temporize, allowing time for both corticosteroid and antibiotic therapy to take effect. These treatment decisions should be coordinated with the receiving obstetrician.

All patients with PROM should be assessed for intra-amniotic infection. Infectious complications should be diagnosed and treated before the mother has overt clinical signs of infection. Preterm PROM is usually treated with intravenous ampicillin (or amoxicillin) and erythromycin.[40] Of note, amoxicillin–clavulanic acid has been found to increase the risk of necrotizing enterocolitis in several studies and is therefore not recommended.[39,40] Treatment of term PROM is indicated when the patient is group B streptococcus positive or has not been tested. The signs and symptoms of chorioamnionitis are late manifestations of advanced infection and are discussed next.

Chorioamnionitis

Chorioamnionitis occurs when vaginal or cervical bacteria ascend into the uterus, instigating an inflammation of the chorion and amnion layers of the amniotic sac.[41] It occurs in 1 to 10% of all pregnancies, and risk factors include prolonged labor, PROM, excessive vaginal examinations, and recent amniocentesis. Box 181-6 summarizes the findings and evaluation of chorioamnionitis. Chorioamnionitis may result in prolonged first- and second-stage labor and decreased responsiveness to oxytocin. Early, aggressive treatment, even before evidence of infection occurs, decreases neonatal morbidity and delays delivery, allowing fetal maturation.[42,43]

Decreased variability of fetal heart rate

Vertical Transmission of Human Immunodeficiency Virus

Emergency deliveries may involve women who are known to be HIV positive in addition to women who are infected but have never been tested. The latter group generally includes pregnant women with little or no prenatal care who are at risk for precipitous delivery. In 2000, between 280 and 370 infants were born in the United States with HIV infection. Of these, 29% were born to mothers undiagnosed with HIV infection before delivery.[44] Transmission may occur in the antepartum, intrapartum, or postpartum (breast-feeding) period. Because intrapartum transmission accounts for up to 75% of vertically transmitted HIV infections, antiretroviral therapy on presentation, even while labor progresses, can decrease vertical HIV transmission.[45] Potential mechanisms of transmission include microtransfusion during contractions, absorption of virus through the mucous membranes, and even invasion through the epithelium. Risk factors for transmission include high viral loads, prolonged rupture of membranes, maternal drug use, vaginal delivery, and breast-feeding (see Table 181-4).[46,47]

In November 2002, the Food and Drug Administration approved the OraQuick Rapid HIV-1 Antibody Test (OraSure Technologies, Bethlehem, Pa).[48] Point-of-care testing for HIV with a median turnaround time of 45 minutes realistically allows the clinician to initiate intrapartum and neonatal antiretroviral therapy when the test result is positive. Serologic confirmation is recommended, but emergent interventions can proceed on the basis of the bedside result.[49] Since 1994, it has been known that immediate treatment during labor can significantly decrease vertical transmission to the newborn.[50]

A positive HIV test result in some cases may allow a change in the method of delivery. Cesarean section decreases the rate of HIV transmission compared with vaginal delivery methods. In a 1999

www.ketabpezeshki.com 66485457-66963820

meta-analysis from the United States and Europe, vertical HIV transmission was decreased by cesarean section with an odds ratio of 0.43 (95% confidence interval, 0.33-0.56). The protective effect of surgical delivery over other delivery methods persisted even when the data were stratified for receipt of antiretroviral therapy.[51] This finding was tempered by an increase in maternal morbidity and mortality in HIV-positive women undergoing cesarean section because of an increased incidence of endometritis, maternal sepsis, pneumonia, and transfusion.[52] Taking into account the risks and benefits, current ACOG and Department of Health and Human Services panel guidelines recommend elective cesarean section for all HIV-infected women with viral loads of more than 1000 copies/mL at 38 weeks of gestation.[53]

Ideally, decisions about the mode of delivery and the need for antiretroviral therapy can be made before the rupture of membranes. The risk of transmission increases after that time and continues to increase as the fetus traverses the birth canal.[53] When antiretroviral therapy and elective cesarean section are used, the likelihood of vertical transmission is reduced by 87% compared with that for women receiving neither intervention.[51]

This relatively new diagnostic and therapeutic burden placed on the emergency physician faced with an imminent delivery is challenging. Data indicate that antiretroviral treatment and the mode of delivery make labor a true emergency for an HIV-positive patient. In addition, pregnant women with advanced HIV disease have a higher incidence of premature births, postpartum endometritis, and perinatal mortality.[47] Currently, the main obstacle to this type of care is the availability of point-of-care HIV testing. Since the late 1990s, the results supporting this approach have become increasingly robust and seem to justify the efforts.[54,55]

Complicated Delivery

Perspective

Complicated deliveries, involving dystocia, malpresentation, and multiple gestations, are potentially life-threatening emergencies. The emergency physician cannot "solve" these obstetric problems with cesarean section and will therefore face the prospect of an extremely high risk vaginal delivery. As expected, these abnormal deliveries increase the risk of fetal and maternal complications. Aggressive attempts to obtain obstetric, neonatal, and anesthesia support are warranted. If the delivery proceeds in the ED, preparations for maternal and neonatal resuscitation should be made rapidly.

Principles of Disease

Knowledge of abnormal labor and its anatomy and physiology is important for the clinician facing a complicated delivery. Intrapartum management skills will enable the physician to proceed with delivery in an efficient, capable manner.

Dystocia and Malpresentation. Dystocia, or abnormal labor progression, accounts for one third of all cesarean sections and half of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency physician, intrapartum management skills are important.

Dystocia can be divided into three etiologic categories. Labor fails to progress when there are problems related to the pelvic architecture (the passage), when there are fetal size or presentation problems (the passenger), and when uterine expulsive forces are inadequate. Although it is useful to consider these causes independently, dystocia is usually caused by a combination of factors. Presentation problems are particularly important because they become apparent during stage 2 of labor and require immediate action.

Table 181-5 Relative Incidence of Malpresentations

MALPRESENTATION	INCIDENCE
Breech presentation	1/25 live births
Shoulder dystocia	1/300 live births
Face presentation	1/550 live births
Brow presentation	1/1400 live births

In order of increasing incidence, brow, face, shoulder, and breech presentations are the most common malpresentations (Table 181-5). True fetopelvic disproportion is much less common. Cesarean section is indicated when labor arrest or cord prolapse coexists with these presentations.[56]

Breech Delivery

Perspective. Breech is the most common malpresentation, occurring in just less than 4% of all deliveries.[57] Three types of breech presentation exist: frank, incomplete, and complete (Fig. 181-8; Box 181-7). The main mechanical problem with breech presentations is that the buttocks and legs do not provide a sufficient wedge, hindering cervical accommodation of the relatively larger head. In addition, because the presenting part does not completely occlude the cervical opening, umbilical cord prolapse may occur.

The terminology for breech deliveries is complicated. By convention, the presentation (frank, incomplete, and complete) is followed by the relationship of the fetus to the birth canal, with the fetal sacrum as a reference point. The mode of delivery also has specific terminology. *Spontaneous breech delivery* refers to vaginal delivery without manual aid, almost always of a small premature infant. *Assisted breech delivery* and *partial breech extraction* are terms that apply when delivery is manually assisted after the umbilicus clears the perineum. The head may be delivered by intrapartum maneuvers or forceps. Complete breech extraction consists of the application of traction to the lower extremities or groin before delivery of the buttocks. This approach is never indicated for a singleton breech because it increases the chances of head entrapment. Confusion arises because the word *complete,* as used here, describes the mode of delivery, not the presentation.

Correlated with this abnormal presentation are several factors: prematurity, multiparity, fetal abnormalities, prior breech presentation, polyhydramnios, and uterine abnormalities.[57]

Overall, one third of breech fetal deaths are believed to be preventable. Asphyxia is often due to umbilical cord prolapse or entrapment of the head. Fetal head and neck trauma can occur if inappropriate delivery techniques are used. Scheduled cesarean section for these patients reduces the potential for ED presentation. However, emergency physicians should be prepared for vaginal delivery of breech presentations in the event of premature or unforeseen labor in the absence of immediate surgical services.[58]

Diagnostic Strategies. Before labor, Leopold's maneuvers facilitate the diagnosis of breech presentation. In the case of breech presentation, Leopold's first maneuver identifies a firm, round mass (the head) in the fundus of the uterus. The third maneuver reveals the softer breech at the pelvic inlet. For the emergency physician, active labor restricts the use of Leopold's maneuvers; thus vaginal examination is required.

The differentiation of a vertex presentation from a breech by tactile vaginal examination is not always simple. Any time a fontanel is not identified on examination, a breech presentation should be suspected. During the vaginal examination, it is helpful to remember that the face and the skull have a complete circle of bone, whereas the anus is flanked by bone on only two sides.

www.ketabpezeshki.com 66485457-66963820

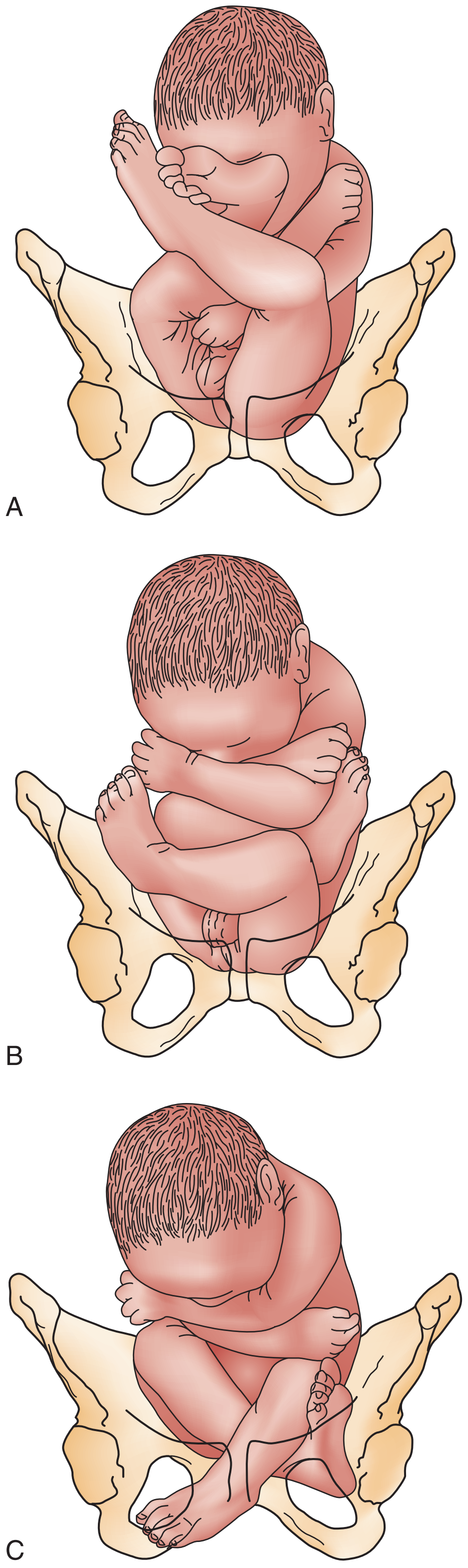

Figure 181-8. Breech presentations. **A,** Frank breech presentation. **B,** Complete breech presentation. **C,** Incomplete breech presentation. (Modified from Cunningham FG, et al: Williams Obstetrics, 19th ed. Norwalk, Conn, Appleton & Lange, 1993.)

If time allows, ultrasound examination is indicated to obtain information on the type of breech presentation, gestational age and fetal weight, and position of the fetal arms and neck.[59] If the fetus has a hyperextended neck, vaginal delivery is associated with a 70% incidence of spinal cord injuries. If possible, labor should be delayed to allow cesarean section.[60] Likewise, if the arms are over the head, they increase the dystocia when the head enters the birth canal. If ultrasound examination reveals anencephaly or massive hydrocephaly, vaginal breech delivery should be allowed to continue because cesarean section is undesirable.

Box 181-7 Breech Presentations

Frank Breech
60-65% of all breech presentations
Hips flexed, knees extended
Buttocks act as good dilating wedge
Incidence of cord prolapse approximately 0.5%

Complete Breech
Least common, occurs in approximately 5% of all breech presentations
Hips and knees flexed
Buttocks act as good dilating wedge
Incidence of cord prolapse is 5-6%

Incomplete Breech
25-35% of all breech presentations
Incomplete hip flexion, single or double footling
Poor wedge
Increased incidence of prolapsed cord (15-18%)

Box 181-8 Vaginal Breech Delivery

Actions to Do as Able
Monitor fetal heart rate.
Obtain a focused history.
Diagnose a breech lie.
Determine cervical dilation and station.
Obtain an ultrasound or plain radiographic study.
Evaluate for prolapsed cord if there is spontaneous rupture of membranes.
Perform an episiotomy.
Flex knees and sweep out legs.
Pull out a 10- to 15-cm loop of cord (room to work) after the umbilicus clears the perineum.
Use the bony pelvis as a means of holding the infant.
Keep face and abdomen away from the symphysis and use rotation to deliver the more accessible arm.
Perform the Mauriceau maneuver.

Actions to Avoid
Inappropriate transfer with delivery en route
Misdiagnosis of cervical dilation
Iatrogenic rupture of membranes (cord prolapse)
Moving of patients or leaving them unmonitored
Traction on the fetus during delivery
Grasping of the fetus by the waist, causing abdominal organ injury
Arm entrapment over head
Neck hyperextension

Management. Premature infants in the breech position often deliver spontaneously without difficulty. As the infant comes to term, dystocia becomes increasingly common. With commitment to a vaginal delivery, knowledge of breech dystocia mechanics may allow atraumatic delivery. The key goals are to maximize the size of the passage and to minimize the dystocia of the after-coming head. Box 181-8 summarizes the actions associated with successful vaginal breech delivery.

The Mauriceau maneuver is the use of the fetal oral aperture to flex the fetal neck and draw in the chin. Because fetal neck extension is associated with cord injuries and worsening dystocia, this

www.ketabpezeshki.com 66485457-66963820

maneuver is useful to ensure a successful vaginal delivery. This maneuver should be attempted only once the fetal elbows and chin have entered the pelvic inlet to avoid inducing the Moro reflex (in which fetal head flexion results in the arms being suddenly extended).[59] While the Mauriceau maneuver is used, the fetal pelvis should be supported to avoid abdominal injuries. Generous episiotomy may even be necessary to facilitate the Mauriceau maneuver in a full-term infant. If the after-coming head cannot be delivered quickly, the chances of good fetal outcome are poor. For term infants, labor arrest, asphyxia, or brachial plexus injuries are potential complications of vaginal breech deliveries.

Shoulder Dystocia

Perspective. Shoulder dystocia is the second most common malpresentation, occurring in 0.6 to 1.4% of all vaginal vertex deliveries.[61] In contrast to a breech presentation, which may be diagnosed in the antepartum period, shoulder dystocia develops in the intrapartum period. Maternal and fetal factors are associated with shoulder dystocia. Maternal factors include diabetes, obesity, and precipitous or protracted labor; fetal factors include macrosomia, postmaturity, and erythroblastosis fetalis. The combination of prenatal data, estimated fetal weight, and fetal biometry cannot reliably identify most deliveries complicated by shoulder dystocia. The fact that shoulder dystocia responds well to a variety of intrapartum maneuvers means that delivery skill is an important determinant of fetal outcome.

The consequences of shoulder dystocia can be devastating. As with breech presentation, infant complications are more common and severe than maternal complications. Traumatic brachial plexus injuries, clavicular fractures, and hypoxic brain injury are all well-documented complications.[61] Maternal complications are related to traumatic delivery and include vaginal, perineal, and anal sphincter tears as well as urinary incontinence.[62]

Diagnostic Strategies

Shoulder dystocia is diagnosed clinically by the inability to deliver either shoulder. The fetal head may appear to retract toward the maternal perineum. This finding is known as the "turtle sign." Traction on the head extends and abducts the shoulders, increasing the bisacromial diameter and worsening the dystocia. Figure 181-9 shows the normal and abnormal relationship of the shoulders to the birth canal and illustrates why the bisacromial diameter is an important element of fetal biometry.

Normally, the shoulders negotiate the maternal pelvis in sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously. In addition to the turtle sign, examination often reveals that the fetal shoulders are on a vertical axis (rather than oblique). These findings in combination with an arrested delivery confirm the diagnosis of shoulder dystocia.[63]

Management. When shoulder dystocia becomes evident, knowledge of intrapartum delivery maneuvers can be lifesaving. Successful vaginal delivery is most likely when a directed sequential approach to each maneuver is used. Rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain help in these areas are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use McRoberts' maneuver (Fig. 181-10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver "walks" the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus pass through the birth canal one shoulder at a time. This method, although requiring very little effort, is successful in 40% of shoulder dystocia cases when it is used alone.[64]

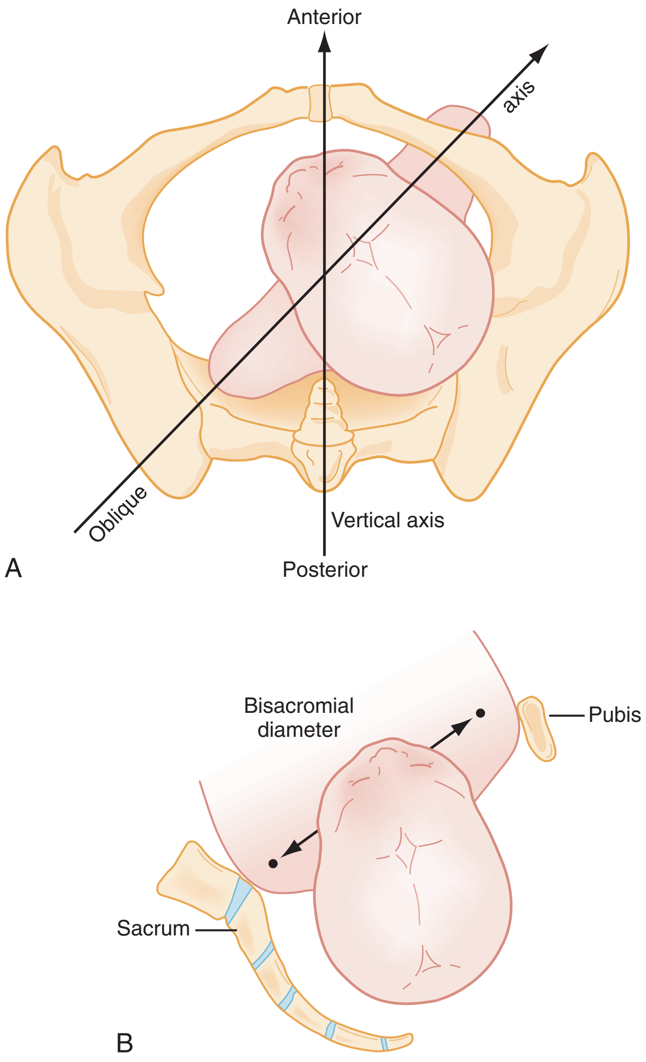

Figure 181-9. **A,** Normal delivery. As the fetal head rotates, the shoulders assume an oblique position and enter the pelvis one at a time. **B,** Shoulder dystocia. Both shoulders attempt to clear the pelvis simultaneously, forcing the bisacromial diameter into the opening.

If McRoberts' maneuver does not free the anterior shoulder, suprapubic pressure may accomplish the goal. Pressure may slip the anterior shoulder beneath the pubis or cause the posterior shoulder to retreat into the hollow of the sacrum. Digital pressure on the posterior shoulder (through the episiotomy) may help facilitate posterior shoulder retreat.

Use of these intrapartum maneuvers resolves most cases of shoulder dystocia. However, if delivery is still impossible, more drastic interventions are warranted. It may be possible to decrease the bisacromial diameter by pushing the most accessible shoulder toward the fetal chest, termed Rubin's maneuver (Fig. 181-11). Often, both shoulders assume the same attitude, decreasing the bisacromial diameter and allowing delivery. Attempts to manipulate the shoulders for Rubin's maneuver may be transabdominal, through the introitus (anterior shoulder), or through the episiotomy (posterior shoulder).

If the shoulders remain undeliverable, the next step is to use Wood's corkscrew maneuver. In this process, the impacted shoulders are released through rotation of the fetus 180 degrees. Fetal rotation is achieved by pushing the most accessible shoulder in

www.ketabpezeshki.com 66485457-66963820

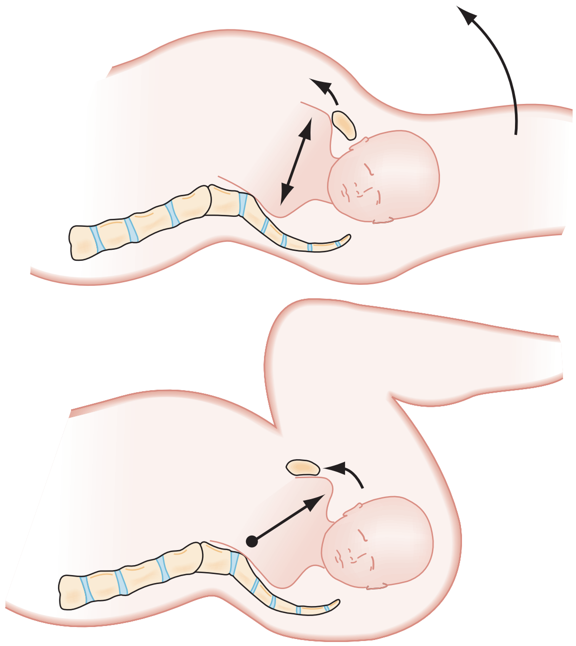

Figure 181-10. McRoberts' maneuver. *Top,* Bisacromial diameter pinned behind pubic symphysis. *Bottom,* Removing the maternal legs from the stirrups and putting the knees up to the chest fulcrum the pubic symphysis over the impacted anterior shoulder.

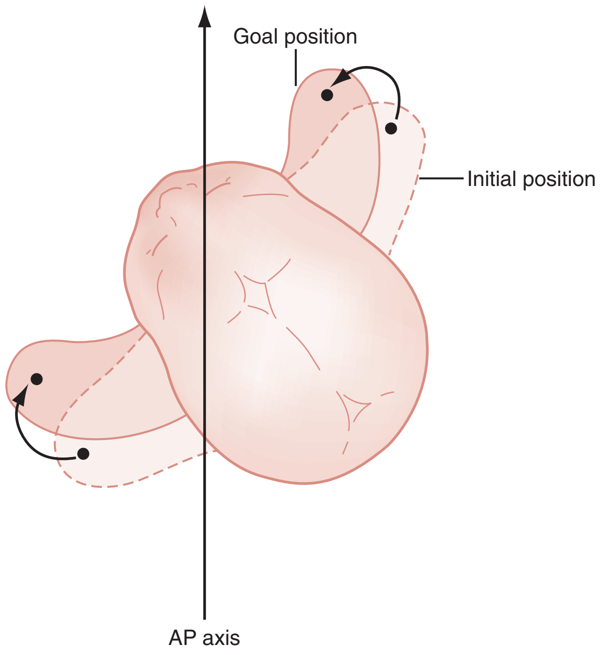

Figure 181-11. Rubin's maneuver decreases the bisacromial diameter. *AP,* anteroposterior.

toward the chest.[65] The fetal axilla can be snared with a digit, or a hand can be slid in along the fetal spine to sweep the hips and generate rotation. Wood's corkscrew maneuver is difficult to perform but should be attempted before reaching for an arm. A slightly oblique anteroposterior position for the shoulders provides the largest passage through the pelvic outlet.

At this juncture, if the fetus remains trapped and several attempts have failed to yield delivery, consideration of delivery of an arm is appropriate. A hand is introduced along the posterior aspect of the posterior shoulder. This would be a tight fit,

Box 181-9 HELPER Mnemonic for Shoulder Dystocia

Help
  Obstetrics, neonatology, anesthesia

  Generous, possibly even episioproctotomy
Legs flexed
  McRoberts' maneuver
Pressure
  Suprapubic pressure, shoulder pressure
Enter vagina
  Rubin's maneuver or Wood's maneuver
Remove posterior arm
  Splint, sweep, grasp, and pull to extension

requiring tactile identification of fetal anatomy. The posterior arm is swept across the chest, bringing the fetal hand up to the chin. Attempts to splint the humerus may prevent fractures and brachial plexus injuries. The fetal hand is grasped and pulled out of the birth canal across the face, delivering the posterior shoulder. The mnemonic HELPER (Box 181-9) has been proposed to help keep these steps organized and to facilitate a sequential approach. These steps successfully deliver almost all cases of shoulder dystocia.

Face, Brow, and Compound Presentations. Face and brow presentations yield a larger engaging aspect of the fetal head and predispose to labor arrest. Although these abnormal presentations can be diagnosed with ultrasonography or Leopold's maneuvers, most are discovered during labor by vaginal examination. Approximately half are discovered during the second stage of labor.

The engaging diameter of the head in vertex position is approximately 0.8 cm less than a face presentation and 1.5 cm less than a brow presentation. Face presentations are described with the chin as a reference point (e.g., mentum anterior). Face presentation is managed expectantly. The obstetric adage "if a face presentation is progressing, leave it alone" arises from the fact that mentum anterior presentations usually deliver vaginally and mentum transverse presentations frequently rotate to become mentum anterior. Brow presentations, occurring when the fetal head is partially flexed, also spontaneously convert to vertex or face presentations in more than 50% of cases.[57]

A persistent mentum posterior face and brow presentation cannot be delivered vaginally if the fetus is full term. The resultant labor arrest requires symphysiotomy or cesarean section. Prolongation of the second stage is the most common outcome of both of these malpresentations at term. For the emergency physician, this prolonged second stage may provide a window during which obstetric help may arrive.

Compound presentations are those in which an extremity enters the birth canal with the head or breech. Small and premature fetuses generally proceed to vaginal delivery without incident.

Labor arrest and umbilical cord prolapse are accepted indications for cesarean section in the setting of face, brow, and compound presentations. Manipulation of a compound presentation, including attempts to reduce the hand or arm, increases the rate of cord prolapse. Therefore, manipulation attempts are contraindicated. Cord prolapse rates are 10 to 20% even without manipulation. Close monitoring and careful examination are indicated.

Multiple Gestations

Perspective. Although twin gestations accounted for less than 1% of all deliveries historically, there has been a recent increase in the frequency of twin and triplet or higher births (65 and 500%, respectively) because of the increasing use of infertility treatments.[66] In 2003 twin deliveries accounted for 31.5 per 1000 live births. Because multiple gestation deliveries have a higher

www.ketabpezeshki.com 66485457-66963820

incidence of preterm labor and low birth weights, both maternal and fetal complication rates are correspondingly increased.[67]

Diagnostic Strategies

Most women with multiple gestations have the situation identified well before the third trimester. In patients who have had little or no prenatal care, bedside ultrasonography allows rapid diagnosis and early preparation. The stages of labor for twins and other multiple gestations are similar to the stages for a singleton. Nulliparous women experience longer labors than multiparous women, with an overall labor duration that is similar to that of singleton pregnancies. Of importance to the emergency physician is a relatively short latent phase of labor, with rapid progression to the active phase. The active phase is usually longer, however. The prolongation of the active phase is due to overdistention of the uterus plus malpresentation and may allow time for obstetric assistance to arrive.

Vertex twin A and vertex twin B occur in approximately 40% of deliveries. In the remaining 60%, one or both of the twins has a malpresentation, usually twin B.[68] Delivery problems with twin B cause most of the preventable perinatal mortality of twin gestation.[69]

Management. The presentation of the twins is an important determinant for the safety of vaginal delivery. Twins who are vertex-vertex, the most common presentation, can be delivered vaginally barring any other obstetric complication. If twin B is nonvertex, some obstetricians recommend cesarean section to prevent delivery-related complications for twin B. External cephalic version may also be attempted to convert twin B to a cephalic, longitudinal lie and then proceed to vaginal delivery. Breech extraction is a third, more difficult, option. The general consensus is that if twin A is nonvertex, cesarean section is the preferred route. In such cases, efforts should be made to delay delivery until an operative approach can be used. Proceeding vaginally can result in interlocking of twins, associated with a high mortality.[70]

The interval between the delivery of twin A and twin B is variable. Although in most cases twin B delivers in minutes, prolonged interdelivery times with good fetal outcomes have been reported. When twin B does not follow rapidly, in utero assessment is important to document fetal well-being. If fetal heart tracings are reassuring, the delivery of twin B (especially nonvertex) should not be hastened. Repeated ultrasonographic evaluation may be used to confirm twin B's presentation and well-being during the interdelivery period.

After every ED delivery, particularly deliveries that are precipitous or that occur in the out-of-hospital setting, the mother should be examined for the possibility of twins. Ongoing labor may be confused with postpartum cramping, only to have twin B and all of the potential complications surprise the clinician. This situation is particularly relevant for women with inadequate prenatal care and low-birth-weight infants.

Umbilical Cord–Related Emergencies

Perspective

Umbilical cord–related complications can occur in normal and abnormal deliveries. Immediate intervention is required to prevent fetal morbidity and mortality. The spectrum of cord-related emergencies includes prolapsed cord, nuchal loops of the umbilical cord, body coils, cord knots, and entangled cords in monoamniotic twins. Cord length is believed to be proportional to fetal activity in utero during the first and second trimesters. Excess cord length increases the potential for umbilical cord complications of all types. Because the umbilical cord supplies the fetus with all of its oxygen, interruption of cord circulation before establishment of fetal respiration is a life-threatening emergency. Fetal asphyxia caused by cord circulation compromise is potentially preventable with appropriate delivery interventions.

Table 181-6 Conditions Associated with Umbilical Cord Prolapse

PRESENTATION	INCIDENCE (%)
Vertex	0.14
Breech	2.5-3.0

Compound	10-20
Face or brow	Rare

Umbilical Cord Prolapse

Clinical Features. Umbilical cord prolapse occurs when the umbilical cord precedes the fetal presenting part or the presenting part does not fill the birth canal completely. Most instances of cord prolapse are unexpected and develop during the second stage of labor.

Cord prolapse has a variable rate of association with different fetal presentations. Compound, shoulder, and breech presentations yield gaps and a relatively poor dilating wedge. Table 181-6 summarizes the rates of umbilical cord prolapse with various fetal presentations. Overall, malpresentations account for 50% of cord prolapse cases; therefore, prolapse may be the first indication of a malpresentation.[71] The reported incidence of cord prolapse ranges from 0.1 to 0.6% of all deliveries, and associated perinatal mortality is estimated to be just below 10%.[72,73]

Diagnostic Strategies. Umbilical cord prolapse may be overt or occult, requiring a pelvic examination to reveal the umbilical cord lying beside the presenting part. The diagnosis also may be made with Doppler ultrasonography. In most cases, the diagnosis is obvious, and the cord is encountered at the perineum or introitus.

Management. Whenever a prolapsed cord occurs with a viable infant, cesarean section is the delivery method of choice. If surgical delivery is available, maneuvers to preserve umbilical circulation should be instituted immediately. The mother should be placed in the knee-chest position with the bed in the Trendelenburg position as the presenting part is manually elevated off the umbilical cord. It is crucial that the mother be instructed to refrain from pushing to avoid further compression of the cord. Placement of a Foley catheter and instillation of 500 to 750 mL of saline into the bladder may help lift the fetus off the cord, particularly in the first stage of labor.[73]

Preparation for an emergency ("crash") cesarean section should be under way. The time from prolapse to surgical intervention is an important factor in fetal outcome. Perinatal mortality rates are significantly higher for out-of-hospital cases (approximately 40%) versus those within a monitored setting (approximately 3%), and outcomes correlate with time from diagnosis to delivery.[73] This finding has implications for the availability of obstetric and surgical backup for the ED.

If surgical delivery cannot be done in a timely fashion, funic reduction (manual replacement of the cord into the uterus) and rapid vaginal delivery may be the only options available. The same maneuvers to decrease cord compression are used, and the umbilical cord is pushed gently, in a retrograde fashion, above

www.ketabpezeshki.com 66485457-66963820

the presenting part. Manipulation and cord trauma is kept to a minimum because the resultant vasospasm can cause fetal hypoxia. After funic reduction, the development of umbilical cord body coils or nuchal loops is common and should be anticipated.[74]

Subsequent to delivery, the physician should be prepared for resuscitation of a distressed newborn. If one is available, a neonatologist should attend the delivery.

Cord Entanglement

The umbilical cord can also become entangled with itself, spontaneously knotting. Umbilical cord knots are related to intrauterine movements early in pregnancy. Approximately 4 or 5% of stillbirths are found to have knots that are believed to have caused fetal demise. Despite this association, cord knots can persist without problems as long as perfusion is maintained.

Loose umbilical cord knots pulled tight at delivery may cause fetal distress. As with cord prolapse, this situation must be resolved quickly to prevent fetal asphyxia. Rapid delivery with avoidance of further cord traction optimizes fetal outcome. No specific interventions exist to deal with this problem.

Long umbilical cords are associated with true knots as well as with entanglements and prolapse. Because the fetal limbs are short and flexed in most presentations, they are rarely involved. Loops around the neck and body do occur, however. Umbilical cord loops can be single or multiple, and there are reports of six nuchal loops. Risk factors for excessive cord length include increasing parity and fetal weight. Although generally benign, they may result in fetal complications, such as nonreassuring fetal status (fetal distress) and respiratory distress.[75]

During delivery, loose nuchal cords should be reduced at the perineum. Loose body coils usually disentangle spontaneously. The reduction process may be aided by slipping them over the extremities or forward over the head. On occasion, loops are tight enough to impede delivery and cannot be reduced. The solution is to cut the clamped cord and deliver the infant rapidly. The high frequency of nuchal loops (one in five births) means that the emergency physician should expect to encounter this problem.

Maternal Complications of Labor and Delivery

Perspective

Maternal complications of labor and delivery include postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, infections, and more. Many of these problems can be managed nonsurgically. When they are severe, however, these complications threaten the reproductive future and the life of the mother and may require emergent surgical intervention.

Postpartum Hemorrhage

Clinical Features. Postpartum hemorrhage is the most common complication of labor and delivery. Defined as hemorrhage of more than 500 mL after vaginal delivery, it affects 5 to 10% of all deliveries and accounts for up to 25% of obstetric deaths.[76] Postpartum hemorrhage is divided into primary and secondary categories. The primary category includes blood loss that occurs within the first 24 hours; the secondary category is hemorrhage 24 hours to 6 weeks after delivery. The clinical picture is as expected with any type of hemorrhage, although because of maternal adaptations during pregnancy, the patient may not show signs of shock until more than 1500 mL of volume is lost.[77]

Differential Considerations. The differential diagnosis of primary postpartum hemorrhage includes uterine atony, genital tract trauma, retained placental tissue, and coagulopathies, or the four *t*'s: tone, trauma, tissue, and thrombin.

Uterine Atony

The most common cause of serious immediate postpartum hemorrhage is laxity of the uterus after delivery. It accounts for 75 to 90% of postpartum hemorrhage cases.[78] Postpartum bleeding from the placental implantation site normally is limited by contraction of the myometrium, constricting the spiral arteries. If the uterus does not contract, ongoing hemorrhage will occur. Predisposing factors include overdistention of the uterus (multiple gestations, fetal macrosomia, and polyhydramnios), prolonged labor, chorioamnionitis, use of tocolytics, and general anesthesia with halogenated compounds. Despite the myriad causes, uterine atony is a diagnosis of exclusion. Physical examination to rule out obstetric trauma and retained products of conception ought to be done before the diagnosis is reached. On examination, the uterus is palpable as a soft, boggy mass.

After other causes have been excluded, therapy to augment myometrial contraction is instituted to prevent further hemorrhage. Two-handed uterine massage may stimulate uterine contraction. One hand exerts pressure transabdominally while the other supports the uterus through the introitus. Uterotonics in conjunction with massage usually provide enough stimuli to control bleeding. Blood is typed, crossmatched, and available for resuscitation should these measures fail.

Maternal Birth Trauma

Maternal birth trauma is the second most common cause of postpartum hemorrhage, accounting for 20% of the cases. Uncontrolled delivery, macrosomia, episiotomy, nulliparity, maternal coagulopathy, operative delivery, prolonged second stage of labor, preeclampsia, and malpresentation may result in maternal birth-related trauma.[79] Although genitourinary structures are most commonly involved, any part of the birth canal–associated anatomy may be injured, with resultant postpartum hemorrhage. Tears and lacerations may involve the perineum, rectum, cervix, vagina, vulva, and urethra. Blood vessels beneath the vulvar or vaginal epithelium can also be injured without frank hemorrhage, resulting in the formation of large, contained hematomas. These hematomas may go unrecognized for hours, gradually enlarging and possibly resulting in hemorrhagic shock. This type of hemorrhage should be suspected whenever there is evidence of ongoing blood loss and no identifiable obstetric site of bleeding (a firm uterus and negative examination findings for lacerations). Delayed postpartum hemorrhage at these sites can also occur and is often a diagnostic challenge. Physical examination may reveal uterine displacement (lateral or cephalad), and confirmation by radiologic means may be used in stable patients. Management, decided in conjunction with specialists, may be expectant, involve vascular embolization, or require surgical intervention, depending on the severity of clinical presentation.[79]

Vaginal tears, especially posteriorly over the ischial spines, are diagnosed early by postpartum exploration rather than hours later when the mother is hemorrhaging. The vulva, including periurethral structures, should be examined. Although minor tears may be left, any laceration involving subcutaneous tissue is repaired with absorbable suture.

The most common sites of tears are within the vaginal, perineal, and rectal structures. Tears are classified as first, second, third, and fourth degree. First-degree tears involve the perineal skin and vaginal mucous membranes without involvement of the underlying fascia and muscle. Second-degree tears extend through the skin into the fascia and muscles of the perineal body but not into the rectal sphincter. Third-degree tears involve the skin, mucous membranes, perineal body, and anal sphincter. Fourth-degree tears extend through all layers, including the rectal mucosa. These

www.ketabpezeshki.com 66485457-66963820

lacerations are also associated with tears in the region of the urethra.

The repair of these tears and the repair of episiotomies are virtually identical. Commonly, repair of the episiotomy is delayed until the placenta is delivered, which allows an uninterrupted approach to potentially complicated repairs. The goal of these repairs is to restore anatomy and to provide hemostasis with a minimum of suturing. Third-degree and fourth-degree tears should be repaired by the obstetrician in an operating room.

Retained Products of Conception

Approximately 10% of postpartum hemorrhage cases are due to retained placental tissue. Normally, the plane of cleavage between the zona basalis and the zona spongiosa results in clean separation of the placenta from the uterus. When this occurs, the placental tissue delivers as a single unit, without evidence of fragmentation. On occasion, accessory placental tissue exists as succenturiate placenta, but this also should cleave normally and deliver spontaneously.

Any placental defect or evidence of accessory placental tissue may signify a retained cotyledon (part of the embryo). Retained fragments prevent myometrial constriction and result in hemorrhage. Inappropriate traction on the placenta during stage 3 of labor can result in tears with retained products of conception, which may cause immediate and delayed postpartum hemorrhage. Ultrasonography may be used in the diagnosis of retained placenta; an empty or fluid-filled uterus provides a high negative predictive value, and an expanded endometrium or solid echogenic mass within the uterus provides evidence of retention.[80,81]

Treatment requires removal of the remnant placental tissue. Digital uterine exploration with blunt dissection of the fragments from the myometrium allows myometrial contraction. Normal placental tissue cleaves away easily, allowing removal. Abnormally adherent tissue is not freed by this mechanism.

Placenta accreta, placenta increta, and placenta percreta describe various degrees of abnormal placental attachment to the uterus. Placental villi may invade the myometrium at the site of implantation, firmly rooting the placenta and obliterating the normal cleavage plane. Thus abnormal attachment results in retained products of conception and postpartum hemorrhage. When the placenta adheres to the myometrium without the intervening decidua basalis, it is termed *placenta accreta*. In *placenta increta,* the villi extend into the myometrium. In *placenta percreta,* the placenta penetrates the full thickness of the myometrium.[82]

The current incidence of placenta accreta is approximately 3 per 1000 deliveries, a relative increase from past decades. Associated risk factors include multiparity, prior cesarean sections, placenta previa, previous curettage, and uterine anomalies.[83]

Coagulopathies

A speedy search for the refractory cause of hemorrhage is warranted because coagulopathies may complicate obstetric hemorrhage. Disseminated intravascular coagulation (DIC) can occur as a consequence of placental abruption, eclampsia, amniotic fluid embolism, postpartum infections, and dilution of clotting factors caused by aggressive volume resuscitation. Also, retained products of conception and dead fetal tissue contain excess thromboplastin, which can initiate DIC. All women with severe postpartum hemorrhage should be evaluated for DIC. As with DIC from nonobstetric causes, clinical signs of bleeding are associated with hypofibrinogenemia, thrombocytopenia, and elevated levels of fibrin split products and D-dimer.[84]

Appropriate management entails hemodynamic support as well as correction of coagulopathies. In fact, investigations have reported the successful use of recombinant factor VIIa for severe cases of postpartum hemorrhage.[85]

Management

Uterine Exploration and Removal of the Placenta

In the face of ongoing hemorrhage and retained products of conception, attempts to remove the placenta manually are indicated. The procedure entails risk of infection, perforation, and increased hemorrhage but may be the most expeditious way to control bleeding. Before beginning, the patient is placed on a monitor, good vascular access is established, and blood products are available. Also, a Foley catheter may be placed to reduce bladder distention and to monitor urinary output.[86] The umbilical cord is traced through the cervical os to the placenta, allowing the identification of a placental margin. The placental membranes are digitally perforated, and the placenta is gradually divided from the myometrium. The palmar surface of the hand is directed toward the placenta, with care taken to avoid uterine perforation. After removal of the placenta, the uterus is explored for retained cotyledons. Removal of any more fragments still present requires curettage of the uterine cavity by an obstetrician. Placenta accreta, placenta percreta, and placenta increta may be diagnosed in this way because these are not digitally dissectible.

Once it is emptied, the uterus is stimulated to contract. Uterine massage, oxytocin, and prostaglandins may be used. Prophylactic antibiotic administration at the time of manual placenta extraction is somewhat debated in the literature. If it is used, a single dose of metronidazole and either ampicillin or cefazolin may be given.[86]

Uterine Packing

Uterine packing to decrease postpartum hemorrhage was widely used previously but now is uncommon. For the emergency physician, this technique may be used to create tamponade, preventing further blood loss. The procedure has limited morbidity and is straightforward. The physician introduces 15 to 20 yards of 4-inch gauze with a ring forceps and packs it into the uterus by a layering technique. A special "uterine packer" is available to help direct gauze high into the uterus but is not necessary. Another option is to place a Foley catheter or Sengstaken-Blakemore tube into the uterus and to instill the balloon with saline.[86]

Opponents of packing point out that an atonic uterus may accommodate a large volume of packing and blood without effective tamponade. Packing may also increase the risk of postpartum infection even when prophylactic antibiotics are given. As with all uterine manipulation and instrumentation, some risk of perforation also exists. Because pelvic embolization and hysterectomy sometimes are not immediately available to the emergency physician, the importance of uterine packing as a temporizing measure is increased.[87]

Pelvic Vessel Embolization

Pelvic bleeding post partum can be difficult to control. Hysterectomy as a solution results in infertility and brings with it all the complications of general anesthesia and major surgery. Radiographic embolization of the bleeding vessels by an interventional radiologist is another option. The procedure does not require an anesthesiologist, operating room, or obstetrician and may be more readily available on an emergent basis. Reported success rates of embolization in control of postpartum hemorrhage range from 95 to 100%.[86]

A catheter is placed in the aorta and fluoroscopically guided to the bleeding sites that are imaged by radiopaque dye. The vessels are embolized with absorbable gelatin sponges placed through the catheter. Common sites of bleeding include the uterine artery, pudendal artery, and hypogastric artery. Because only the smallest involved branches are embolized and recanalization usually occurs, future reproductive capability is generally preserved.[88]

www.ketabpezeshki.com 66485457-66963820

Uterotonic Agents

Although they are commonly applied on delivery of the placenta, uterotonic agents also have special application in the case of postpartum hemorrhage. Uterotonics, such as oxytocin, ergot alkaloids, and prostaglandins, control bleeding by inducing myometrial contraction. Oxytocin is considered to be first-line treatment, given either intramuscularly or intravenously. Ergot alkaloids, such as methylergonovine and ergotamine, may induce hypertension and are therefore contraindicated in patients with preeclampsia or other comorbid conditions. Finally, prostaglandins may also be used (e.g., misoprostol), although they have shown no clear advantage over oxytocin or ergot alkaloids in published reports.[86]

Hysterectomy

Most postpartum hemorrhages are controllable with uterotonics and massage or uterine exploration for products of conception. Rarely, hemorrhage continues despite the interventions outlined. Life-threatening obstetric bleeding may require emergency hysterectomy. The desire to preserve the patient's reproductive capabilities should not be given priority if her life is in jeopardy.[89]

Uterine Inversion

Perspective. Uterine inversion is an uncommon but serious complication of delivery that occurs during stage 4 of labor. The resultant postpartum hemorrhage can be severe and life-threatening, accounting for a maternal mortality rate of up to 15%. Uterine inversion is relatively rare, complicating 1 in 2000 deliveries.[90] It is classified by duration as well as by degree of inversion. Risk factors include excessive fundal pressure during delivery, forceful traction on the umbilical cord (especially in conjunction with a fundal placenta), placenta accreta, maternal congenital abnormalities of the uterus, use of magnesium sulfate in the antepartum period, and primiparity.[90,91]

Clinical Features. Clinically, the patient notes the sudden onset of severe abdominal pain. Abdominal examination reveals tenderness and an absence of the uterine corpus, which is potentially visualized at the cervical os or bulging from the introitus. Profuse bleeding leading to hemodynamic instability can also occur. Ultrasound examination may assist in the diagnosis. Once uterine inversion is identified, the appropriate mobilization of resources should begin simultaneously with efforts to re-establish the correct anatomic position of the uterus.

Management. As with other causes of postpartum hemorrhage, initial management involves aggressive fluid resuscitation.

The highest likelihood for successful repositioning of the inverted uterus is immediately after inversion occurs. If the placenta is still adherent, it should not be removed until after repositioning. Removal of the placenta while the uterus is inverted is associated with excessive blood loss. The initial attempt to reposition the uterus should be to push the fundus upward through the introitus. Digital pressure should be directed toward the mother's umbilicus along the long axis of the uterus. Contraction of the cervical uterine segments can create a muscular ring, preventing repositioning. Therefore, all uterotonic agents should be withheld immediately on diagnosis of uterine inversion.

If initial attempts fail and a cervical ring develops, pharmacologic attempts to relax the uterus are indicated. Sedation and tocolytics can be used to facilitate uterine replacement. Terbutaline and magnesium sulfate have been used successfully to relax cervical rings. When the uterus has been repositioned, the muscle relaxants should be halted, and oxytocin and prostaglandin therapy should be initiated. Firm manual pressure through the introitus should be maintained until uterine contraction begins, the cervical ring contracts, and the uterus can no longer invert. If all these measures fail and surgical backup becomes available, halogenated anesthetics may be used to induce relaxation of the cervical rings with or without an attempt at surgical repair.[90] Once the uterine inversion is resolved, an assessment must be made to screen for uterine perforation, adherent placenta, and vaginal lacerations.[79]

Uterine Rupture

Perspective. Criticism of the high rate of cesarean delivery in the United States has led to an advocacy of vaginal birth after cesarean (VBAC). Prior cesarean section is no longer an automatic indication for repeated cesarean delivery. The high success rate and relative safety of VBAC are countered partly by the risk of uterine rupture. Dehiscence of a surgical scar occurs in 0.6% of VBAC deliveries.[92] As more women have VBAC, emergency physicians can expect to encounter uterine rupture, which is associated with high morbidity and mortality rates.

Clinical Features. Uterine rupture is an unpredictable event occurring late in pregnancy or as stage 1 of labor transitions to the active phase. It is defined as a full-thickness uterine wall perforation. The severity of rupture ranges from simple scar dehiscence to complete fetal extrusion. It may be spontaneous, but it is most often linked with previous uterine surgery.[93] Other risk factors for uterine rupture include congenital uterine abnormalities, trauma, and medications used for labor induction and abortions.[79] As the degree of fetal expulsion through the rupture increases, the fetal mortality rate increases as well. Minimal fetal extrusion results in a perinatal mortality rate of less than 1%, whereas complete extrusion results in a 10 to 20% mortality rate. Maternal death is rare, but significant hemorrhage is common, complicating one third of cases. Maternal genitourinary injury may also occur in association with uterine rupture.

Diagnostic Strategies and Difficulties. The diagnosis of uterine rupture may be difficult because pain is not always present. In fact, clinical presentation of uterine rupture ranges from nonreassuring fetal heart rate patterns to frank maternal hemorrhagic shock.[79] Intrapartum vaginal bleeding may signal the problem, but its absence by no means precludes rupture. Prolonged fetal heart rate deceleration, indicating fetal distress, is the most reliable sign of fetal extrusion.[80] Emergency ultrasonography may reveal a protruding amniotic sac, hemoperitoneum, or the site of myometrial rupture; however, good sensitivity data are lacking.[93]

Management. If uterine rupture is suspected, delivery should be hastened to limit fetal hypoxia. Emergency cesarean section is the best method to speed delivery and to repair the injury. The ACOG guidelines for uterine rupture identify a 30-minute window of opportunity that maximizes fetal outcome.[94] At surgery, the maternal condition dictates whether uterine repair or hysterectomy is indicated. In the absence of opportunity for emergency laparotomy, appropriate interventions remain speculative. Uterotonic agents may exacerbate the rupture and are contraindicated.

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare and catastrophic complication of labor and delivery. The incidence rate is 6.0 and 14.8 per 100,000 in primigravid and multiparous deliveries, respectively.[95] Although the mechanism is not well understood, it is thought to involve the spread of amniotic fluid through the maternal vasculature, activating either a complement or anaphylactic cascade. Cesarean delivery, forceps- or vacuum-assisted delivery, uterine rupture, eclampsia, placenta previa, and placental abruption have been found to have a significant association with amniotic fluid embolism. Patients will demonstrate moderate to severe pulmonary hypertension, right ventricular failure, and, in severe cases, left ventricular failure. The diagnosis is clinically evident during labor, during delivery, or within 48 hours of delivery. It is characterized

www.ketabpezeshki.com 66485457-66963820

by the sudden onset of dyspnea, hypoxia, altered mental status, seizure, hemorrhage (from coagulopathy), fetal compromise, or cardiovascular collapse. DIC occurs in approximately 50%, and both maternal and fetal mortality rates are high. Treatment is generally supportive and may include assisted ventilation, central hemodynamic monitoring, vasopressors or inotropes, and blood products.[96-99]

Postpartum Endometritis

Perspective. Puerperal infections affect 5% of all vaginal deliveries and 10% of all cesarean sections. Operative delivery, prolonged rupture of membranes, lack of prenatal care, prolonged stage 2 labor, use of intrauterine monitoring, and frequent vaginal examinations have been linked to these ascending gynecologic infections.[100] It is estimated that sepsis results in up to 15% of maternal deaths worldwide.[101] Causative organisms for these infections include gram-positive cocci and gram-negative coliforms. Less commonly, *Chlamydia* and *Mycoplasma* species have been implicated.

Clinical Features. Endometritis is the most common puerperal infection, usually developing on the second or third day post partum. Typically, the lochia has a foul odor and the white blood cell count is elevated. Fever and abdominal pain indicate greater severity of infection, often warranting inpatient care and intravenous antibiotics. A coexistent surgical wound infection is often present. A search for retained products of conception is indicated, particularly if bleeding is ongoing.

Management. Treatment is empirical and directed at gram-positive, gram-negative, and anaerobic organisms. A combination of clindamycin and an aminoglycoside is recommended. Another commonly used antibiotic regimen is a second- or third-generation cephalosporin plus metronidazole.[102] Most patients with postpartum endometritis require admission.

Peripartum Cardiomyopathy

Perspective. For unclear reasons, the peripartum period is associated with the relatively sudden onset of cardiomyopathy in healthy women without evidence of prior cardiac disease. Estimates indicate that peripartum cardiomyopathy (PPCM) occurs in 1 of 4000 pregnancies; reported risk factors include advanced maternal age, preeclampsia, gestational hypertension, multiparity, and African American race.[103] Proposed causes include viral, immunologic, hormonal, toxic, and genetic factors, but no specific cause is found in most cases. Reported mortality rates for PPCM range from 0 to 19%.[104]

Clinical Features. Symptom onset varies, as does the severity of the cardiomyopathy. Onset is usually days to weeks after delivery, and symptoms range from mild fatigue to acute pulmonary edema. PPCM is often unrecognized in its milder form, leading to the consensus that the condition may be more prevalent than reported. Dyspnea on exertion, orthopnea, and fatigue may be easily misinterpreted as normal in a mildly anemic woman who is breast-feeding a new infant at home. The clinician should not dismiss these symptoms because severe congestive heart failure, thromboembolism, and dysrhythmias may ensue.

Management. Treatment with diuretics, vasodilators, and oxygen relieves the symptoms in many cases. Angiotensin-converting enzyme inhibitors are contraindicated if PPCM occurs during the last month of pregnancy (owing to teratogenicity) but should be considered a mainstay of treatment post partum. Amlodipine (a dihydropyridine calcium channel blocker) may also have a role in the treatment of PPCM.[105,106]

Cardiac function returns to normal in half of patients with PPCM during the following 6 months. Others have residual left ventricular dysfunction, although the overall survival rate at 5 years is 94%.[107] The presence of cardiomyopathy after one pregnancy does not predict recurrence during subsequent pregnancies.[108] Most obstetricians recommend against future pregnancies, however, especially if some residual cardiac function impairment exists. If such a pregnancy cannot be avoided, it should be considered high risk and observed closely.

Postpartum Depression

Perspective. Postpartum depression is likely to be underdiagnosed, but it is estimated that it affects 10 to 15% of mothers. Although in many cases it is self-limited, the condition has been recognized as having important consequences for the mother, infant, and family. Risk factors for postpartum depression include previously diagnosed depression and neuroticism, inadequate spousal support, adverse socioeconomic factors, recent life stressors, and emergency delivery.[109]

Clinical Features. Postpartum depression patients present with symptoms not unlike those of other major depressive disorders. These symptoms include depressed mood, anhedonia, loss of appetite, insomnia, fatigue, decreased concentration, feelings of guilt and worthlessness, and suicidal ideation.[110] Most women with postpartum depression do not have vegetative signs or symptoms. Symptoms peak at 10 to 12 weeks post partum, although some cases are diagnosed up to 1 year post partum.[111]

When postpartum depression is unrecognized, these women are at high risk for suicide and may come to the ED with overdoses or other manifestations of a suicidal attempt.

Management. Early identification and referral are the key components of therapy. Dismissal of postpartum fatigue as normal, without consideration of the diagnosis of postpartum depression, can be disastrous. Not only does this condition contribute to marital discord, maternal risk for suicide, and even infanticide, but studies have shown that children of depressed mothers have an increased incidence of delayed cognitive, psychological, neurologic, and motor development.[112] Therefore, sensitivity to the possibility of postpartum depression is crucial to successful treatment.

KEY CONCEPTS

- ED deliveries should be considered high risk. Antepartum hemorrhage, PROM, eclampsia, premature labor, precipitous delivery, malpresentation, and umbilical cord emergencies are overrepresented in emergency deliveries.
- Women in labor who present to the ED are generally best cared for in the obstetric suite. Women with the urge to push or with the head of the infant crowning are at imminent risk of delivery, which should take place in the ED. The transfer of a woman with an impending high-risk delivery to a perinatal center ought to be tempered by clinical and medicolegal judgment.
- Most ED deliveries require only basic equipment to cut and clamp the umbilical cord and to dry and suction the infant. However, the ED should have the equipment and staff available to care for a newborn requiring further resuscitation.
- Maternal complications of labor and delivery include obstetric trauma, postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, coagulation disorders, and infections. Many of these problems can initially be managed nonsurgically in the ED.
- Deliveries complicated by dystocia, malpresentation, or multiple gestations are life-threatening emergencies. The clinician should develop strategies to treat each of these potential complications of delivery.

Section Three
THE GERIATRIC PATIENT

CHAPTER 182
The Elder Patient

Diane M. Birnbaumer

There are no diseases of the aged, but simply diseases among the aged.

Leonard Larson, 1960

PERSPECTIVE

The population of the United States is aging, with the proportion of people older than 65 years increasing at twice the rate of younger people. In 2010, 13% of the population was older than 65 years, and by 2045 one in five people are expected to be older than that age.[1] In 2008 the first baby boomer turned 62 years old, and as of January 2011 this so-called silver tsunami began to qualify for Medicare.

These changing demographics affect the practice of emergency medicine. In 2008 elders accounted for 46% of the 123 million emergency department (ED) visits, and ED visits in this age group are increasing by one third every 10 years.[2] Elders presenting to the ED are more likely to arrive by ambulance, to have a more emergent condition than younger patients, and to require longer evaluations.[3] One third of these patients are admitted, many to the intensive care unit.[4] As the number of ED visits by elders continues to climb, the health care impact will be enormous.

PRINCIPLES OF DISEASE

Physiologic Changes of Aging

Physiologic changes of aging affect virtually every organ system and have many effects on the health and functional status of elders (Table 182-1). Heart disease is the leading cause of hospitalization and death.[5] Increased peripheral vascular resistance with aging leads to an increased risk of hypertension. Decreased inotropic and chronotropic cardiac functioning compromises the patient's ability to respond to physiologic stressors. Atherosclerosis is common and contributes not only to the rate of heart disease but also to the risk of vascular conditions (e.g., stroke, mesenteric ischemia, peripheral vascular disease, aortic dissection, and abdominal aortic aneurysm).

Because of several changes that occur with aging, elders are at higher risk for infections. Prostate disease in men and incomplete bladder emptying in women with pelvic floor abnormalities predispose to urinary tract infections. Microaspiration increases the risk of pneumonia, and fragile, aging skin prone to injury and breakdown increases the risk of infections of the skin and soft tissues. *Immunosenescence* of cell-mediated immunity predisposes patients to reactivation of latent diseases (e.g., tuberculosis) and may be associated with increased susceptibility to neoplasms. Cancer is the second most common cause of hospitalization and death in older patients.[5]

Fractures are the fifth leading cause of hospitalization, reflecting the high rate of osteoporosis, particularly in women.[4] Arthritis is the most prevalent outpatient disease in elders because of the wear on cartilaginous joints, particularly of the knees, hips, and hands.[4] Arthritis greatly affects quality of life, and these patients report fair or poor health approximately three times more often than patients without arthritis do.

Although the physiology of aging often affects a patient's functional status, laboratory values are usually within the normal range. Abnormal laboratory values in elders should be evaluated as abnormal findings and should not be attributed to "normal effects of aging."

Pharmacologic Considerations

Polypharmacy, drug interactions, and misuse and abuse of medications in elders are crucial health care issues. Elders currently consume more than 30% of the prescription drugs in the United States, and this figure is projected to increase to 50% by 2020. More than 40% of elders use five or more drugs weekly, and more than 10% use ten or more.[6,7]

Although multiple medications may be necessary to treat the medical problems that occur with aging, significant adverse health effects may result. Underlying medical problems, multiple physicians, changing pharmacokinetics of aging, and treatment of side effects of one medication with another drug are all contributory. Twelve percent to 30% of admitted elders have adverse drug reactions or interactions as a primary or major contributing factor to their admission, and 25% of these drug reactions or interactions are serious or life-threatening.[6,7]

Pharmacokinetics may change with age. Altered gastrointestinal motility and blood flow, decreased lean body mass, increased proportion of adipose tissue, decreased creatinine clearance, and decreased hepatic blood flow may alter the absorption, distribution, and clearance of medications. Despite these changes, the bioavailability of most medications is not significantly altered in elders. Medication interactions and side effects pose significant problems, however, particularly because many elders take multiple medications. Emergency physicians may unwittingly contribute to this problem by adding a new medication at discharge that may have an adverse drug interaction with a patient's preexisting medications. In addition, the altered pharmacokinetics in elders necessitates caution when medications are administered in the ED, particularly sedative-hypnotics and narcotics. For these agents, a good rule of thumb is "start low and go slow."

Several medications frequently used in the outpatient elder population are considered to be "potentially inappropriate medications." This list includes but is not limited to narcotic analgesics, nonsteroidal anti-inflammatory agents, sedative-hypnotics,

www.ketabpezeshki.com 66485457-66963820

Table 182-1 Physiologic Changes of Aging and Potential Effects

PHYSIOLOGIC CHANGE	POTENTIAL EFFECT
Nervous System	
Decreased efficiency of blood-brain barrier	Increased risk of meningitis Potential for exaggerated medication responses
Decreased response to changes in temperature	Impaired thermoregulation
Alteration of autonomic system function	Variations in blood pressure; risk of orthostatic hypotension Reduced erectile function Urinary incontinence
Alterations in neurotransmitters	Slowing of complex mental functioning
Skin and Mucosa	
Atrophy of all skin layers	Decreased insulation Increased risk of skin injury Increased risk of infection
Sweat glands decreased in number or activity	Potential for hyperthermia
Musculoskeletal System	
Progressive bone loss	Increased risk of fractures
Atrophy of fibrocartilaginous and synovial tissues	Joint instability and pain Impaired balance and mobility
Decrease in lean body mass	Alteration in pharmacokinetics
Increase in proportion of adipose tissue	Alteration in pharmacokinetics
Immune System	
Decrease in cell-mediated immunity	Increased susceptibility to neoplasms Tendency to reactivate latent diseases
Decreased antibody titers	Increased risk of infection
Cardiovascular System	
Decreased inotropic response	Less efficient response to myocardial wall stress
Decreased chronotropic response	Decreased maximal heart rate
Increased peripheral vascular resistance	Increased blood pressure
Decreased ventricular filling	Changes in organ perfusion
Pulmonary System	
Decreased vital capacity	
Decreased lung and airway compliance	Increased airway resistance
Decreased chemoreceptor response to hypercapnia or hypoxemia	Potential for rapid decompensation
Decreased ventilatory drive	Decreased Pao_2 and increased $Paco_2$
Decreased diffusion capacity	Decreased Pao_2
Hepatic Function	
Decrease in hepatic cell mass	Reduced ability to regenerate
Decrease in hepatic blood flow	Alteration in pharmacokinetics
Alterations in microsomal enzyme activity	Alteration in pharmacokinetics
Renal System	
Decrease in renal cell mass	Decreased drug elimination
Thickening of basement membrane	Decreased drug elimination
Reduced hydroxylation of vitamin D	Risk of hypocalcemia, osteoporosis
Decrease in total body water	Alteration in pharmacokinetics
Decreased thirst response	Risk of dehydration and electrolyte abnormalities
Decreased renal vasopressin response	Risk of dehydration and electrolyte abnormalities
Gastrointestinal System	
Decrease in gastric mucosa	Increased risk of gastric ulcer
Decrease in bicarbonate secretion	Increased risk of gastric ulcer
Decrease in blood flow to gastrointestinal system	Increased risk of perforation
Decreased epithelial cell regeneration	Longer healing times

www.ketabpezeshki.com 66485457-66963820

muscle relaxants, and antihistamines.[8-10] These agents are generally not recommended for use in this population of patients and should be used sparingly.

The medications most often implicated in adverse reactions in elders in the ambulatory setting are cardiovascular medications, followed by diuretics, nonopioid analgesics, hypoglycemics, and anticoagulants.[11,12] Caution should be used in prescribing any of these classes as they can contribute to morbidity and mortality in this age group.

The various analgesic medications used in the elderly can cause a wide range of adverse reactions and interactions. Narcotics and sedative-hypnotic agents can decrease cognition and increase the risk of falls and accidents. Nonsteroidal anti-inflammatory drugs (NSAIDs) may have serious and potentially lethal side effects. The toxicity of NSAIDs includes azotemia, worsened hypertension, and congestive heart failure as a result of sodium retention. Gastrointestinal toxicity ranges from bleeding to perforation.[13] The data support use of extreme caution in prescribing NSAIDs. These complications can be seen in patients taking widely available over-the-counter formulations of these drugs. The significant increase in cardiovascular risk with the use of cyclooxygenase 2 inhibitors has led to a dramatic decrease in the use of these agents.

Because of these concerns, pain management in the elderly can pose a challenge. Although a “first, do no harm” philosophy is laudable, treatment of pain is one of the most important remedies physicians have to offer. Three major considerations influence the choice of medication for elderly patients. First, chronic pain (e.g., arthritis pain) may require treatment different from that of an acute painful condition (e.g., wrist fracture). Second, the patient’s underlying medical problems, social situation, and baseline functional status need to be considered.[14] Third, starting with low doses, then titrating upward to effect, is the safest strategy.

Overall, acetaminophen has the highest safety profile in elders and often is the drug of choice for chronic painful conditions (e.g., degenerative joint disease). Although inadvertent excessive dosing can occur, acetaminophen is safe and should be considered first-line management for chronic pain and acute conditions causing mild to moderate pain.

NSAIDs effectively ease pain, but these agents have a ceiling analgesic effect. Increasing the dose increases the risk of side effects without increasing the analgesic benefit. These agents in low doses should be used as second-line agents after acetaminophen in chronic or acute painful conditions.

Narcotics may be necessary for acutely painful conditions and chronic conditions refractory to acetaminophen or NSAIDs. The common side effect of constipation can be a problem, and older patients need to be instructed to exercise regularly, to eat high-fiber foods or supplements, and to remain well hydrated. Because these agents may decrease cognition, start with low doses and titrate upward as needed, and patients and their families should be told of the increased risk of falls associated with these agents.

Psychosocial Issues

The possibility of drug dependence and ethanol abuse should be considered in the treatment of elders. These patients often present with mental status or gastrointestinal complaints or after falls or other trauma. Ethanol dependence is a factor in elders who present in the ED, and dependence on prescription drugs, particularly sedative-hypnotics, is also more prevalent than suspected.[15,16] The routine outpatient use of sedative-hypnotics should be avoided and duration limited; dependence on these drugs may cause decreased cognition, and withdrawal from these agents can be life-threatening.

Psychiatric disease in elders often is manifested in atypical fashion. Depression, a common problem, may be manifested as agitation, anxiety, and somatic complaints in addition to the typical depressive symptoms.[17,18] Depression often follows chronic illness, loss of physical mobility, diminished cognitive function, bereavement from the death of a spouse or long-time friend, and financial pressures, all of which are common features of old age. Social isolation and loss of independence produce a sense of helplessness and hopelessness that may result in suicidal ideation or action. Certain types of depression, such as “late-life delusional depression” and involutional depression, occur exclusively in old age. In addition, depression may be caused by medication side effects or reversible physiologic conditions (e.g., thyroid disease and malnutrition). Elders often respond to pharmacologic treatment of depression but are prone to the development of adverse effects from antidepressants; selective serotonin reuptake inhibitors seem to be safer. A phenomenon known as *sundown syndrome* occurs in elderly demented patients, who become highly agitated and disoriented after dark when visual sensory input is diminished and the environment becomes unfamiliar.

EVALUATION AND CLINICAL FEATURES

The evaluation of elders is often difficult. Elders living independently have an average of three medical problems, which increases up to ten for those living in care facilities. Underlying illnesses complicate the evaluation. Use of ancillary services can be increased by 50% in elders, most likely because of vague or atypical presentations and complicated medical backgrounds.

History

Obtaining a medical history from an elder can require meticulous and painstaking work. Cognitive and physical deficits should be recognized, and physicians often need to be creative and thorough to obtain adequate information.

Cognitive deficits may compromise an elder’s recall and result in an inaccurate medical history. Enlistment of family members, consultation with the patient’s primary care physician, and review of past medical records may be necessary. Particular attention should be paid to past medical and surgical problems and to the patient’s current medications, including over-the-counter and herbal preparations.

Physical deficits also may impede the history-taking process. Sequelae from previous strokes (e.g., aphasia) are usually obvious. Hearing impairment affects communication and can lead to potentially dangerous misunderstandings. Elders tend to lose high-frequency hearing earlier than other ranges, so physicians should lower the pitch of their voice and speak loudly while ensuring the patient’s privacy. Hearing loss can be embarrassing for the patient; thus the physician should address the issue with sensitivity to allow adequate communication while maintaining the patient’s dignity.

Physical Examination

Because of the physiologic changes that occur with aging, the physical examination may be misleadingly benign in an elder, despite the presence of a potentially lethal illness. In addition, medications may alter the response of elders to physiologic stressors. Antihypertensives, particularly beta-blockers, may alter the patient’s ability to mount tachycardia in response to hypovolemia or sepsis or may predispose the patient to hypotension.

Of elders with a serious infection, 30% present with a blunted or absent fever response.[19] The temperature measurement should be accurate. As an oral temperature may be spuriously low, a rectal temperature should be measured when the presence of fever is uncertain in a patient with a possible infection. When fever is present, elders are much more likely to have a serious (nonviral)

www.ketabpezeshki.com 66485457-66963820

infection than are younger patients.[20] Of febrile elders presenting to an ED, 89% have an infectious disease.[20] Approximately one third are respiratory tract infections, one fifth are urinary tract infections, and nearly one fifth are bacteremia or sepsis.[20] Fever in an elder should be taken seriously, with appropriate ancillary testing and a low threshold for admission. Also, a lack of fever does not exclude infection.

DIAGNOSTIC STRATEGIES

Because of the difficulty in obtaining accurate histories and the often poor sensitivity of physical findings in elders with significant underlying disease, more diagnostic tests are generally obtained for these patients than for their younger counterparts who present with similar complaints. This increased use of resources is appropriate because the accuracy and timeliness of diagnosis are critical in elders, who suffer greater morbidity and mortality with delays in definitive treatment.

SPECIFIC DISORDERS

Myocardial Infarction

The incidence of atypical presentation of acute myocardial infarction (AMI) increases with age.[21-23] In patients older than 85 years, atypical presentation of myocardial infarction may be anticipated, and a lack of chest pain may be the rule. Only 2 to 6% of elders with AMI, however, have an asymptomatic presentation.[21] A painless myocardial infarction is more common with increasing age and occurs more often in women than in men.[21-23] Sudden onset of dyspnea may be the only presenting complaint in elders with myocardial infarction. Other presenting complaints include syncope, influenza-like symptoms, nausea, vomiting, confusion, and generalized weakness.[22,23] As the prognosis for AMI in elders who present atypically is the same as that for elders who present typically, these atypical presentations are not more benign.

Infections

Elders are prone to infectious diseases more than younger patients are, with both greater morbidity and higher mortality. Common infections occur regularly, but aging causes this population to be more susceptible to unusual organisms. Although immunosenescence is a contributory factor, predisposing illnesses and institutionalization are more significant causes of this increased risk. Hospitalization increases the risk of nosocomial infection. Instrumentation and catheterization are also significant risk factors for acquisition of infectious diseases.

Evaluation of infections may be difficult because up to nearly half of elders with proven bacterial infections do not have a fever at presentation.[24] In addition, the sensitivity of an elevated white blood cell count and bandemia is poor, approximately 44% and 32%, respectively.[24]

Several infections, particularly pneumonia, urinary tract infections, and sepsis, occur more often in elders. Pneumonia is one of the ten leading causes of hospitalization and death.[5] The elderly are more prone because of decreased vital capacity, decreased lung and airway compliance, less ventilatory drive, and poor ciliary function. Combined with decreased cough response and increased esophageal reflux with microaspiration, pneumonia is the leading cause of hospitalization due to infection in elders. Pneumococcus is still a common cause, but gram-negative organisms are also common, as are mixed infections. Reactivation of tuberculosis also should be considered in this age group.

Urinary tract infections are common in elders. The incidence of bacteriuria is 20% in men older than 70 years and 20% in women 65 to 70 years of age, increasing to 23% and 50%, respectively, in men and women older than 80 years.[25] Laxity of the pelvic floor and urinary incontinence are significant risk factors in women, whereas prostate enlargement is a significant risk factor in men. The incidence of urinary tract infections increases dramatically in patients with chronic indwelling catheters.

Table 182-2 Differential Diagnoses of Abdominal Pain in Elderly Patients

DISORDER	INCIDENCE (%)
Cholecystitis, biliary colic	12-41
Nonspecific abdominal pain	9.6-23
Appendicitis	2.5-15.2
Obstruction	7.3-14
Hernia	4-9.6
Perforation	2.3-7
Pancreatitis	2-7.3
Diverticular disease	3.4-7

Abdominal Pain

Abdominal pain is arguably the most difficult presenting complaint to evaluate in elderly patients. Despite this, most patients have a specific diagnosis made in the ED. Two thirds of elders with abdominal pain are admitted, and nearly one fifth go directly to the operating room.

The differential diagnosis (Table 182-2) of abdominal pain in the elderly differs significantly from that in younger patients, particularly in regard to the number of serious and potentially life-threatening causes. The pathologic condition in more than 60% is surgical in nature, a rate nearly double that of younger patients. There is a tenfold higher risk of mortality compared with younger patients.[26]

Because of the physiologic changes of aging, even life-threatening causes of abdominal pain may be manifested with few or no alarming findings. Elders may complain of vague abdominal pain despite the occurrence of a catastrophic process. The complication rates of typically benign processes in younger patients are dramatically higher in older patients. With aging, the abdominal musculature decreases, and patients are less able to manifest guarding and rebound. In addition, the omentum shrinks and is less able to contain intra-abdominal processes. Atherosclerotic disease, with its resultant decrease in blood flow, causes increased perforation rates in diseases such as cholecystitis and appendicitis. This increased rate of vascular disease also contributes to higher rates of vascular causes of abdominal pain, such as mesenteric ischemia and leaking or ruptured abdominal aortic aneurysms.[27] The high prevalence of gallstones in elders leads to an increased risk of cholecystitis.

Because of the vague presentation and high rate of serious disease, evaluation of an elderly patient with abdominal pain often requires an extensive battery of laboratory and radiographic tests.[28] Elders with potentially catastrophic intra-abdominal processes may not present with a fever or an elevated white blood cell count.[26] As a result, ancillary diagnostic ultrasonography, computed tomography, radionuclide studies, and, occasionally, angiography may be vital. Because many elders with abdominal pain have a serious disease, consider admission and close observation when symptoms persist and the diagnosis remains unclear. If the patient is not admitted, a period of ED observation or re-evaluation within 12 hours is prudent.

www.ketabpezeshki.com 66485457-66963820

Major Trauma

Major trauma in elders (see Chapter 39) is relatively uncommon, constituting 8 to 15% of cases in major trauma databases. Elder trauma patients, however, experience higher mortality and poorer functional recovery for a given trauma score.[29-32] For virtually any trauma in elderly patients, the circumstances leading to the injury need to be determined and the circumstances questioned. Trauma in the elderly may be due to potentially serious or life-threatening medical causes, such as syncope, hypovolemia due to dehydration or bleeding, cardiac or cerebrovascular disease, or medications.[29] Motor vehicle crashes, particularly involving a single vehicle, may result from transient loss of consciousness due to dysrhythmias, syncope, medication side effects, transient ischemic attacks, strokes, or myocardial infarctions.[31] These serious medical problems require simultaneous diagnosis and treatment in the setting of trauma and may be as important as or more important than the traumatic injuries.

The presence of comorbid illness and the limited physiologic reserve in the cardiopulmonary and renal systems often complicate the trauma resuscitation in this age group. More aggressive ventilatory support and early use of invasive hemodynamic monitoring are indicated to guide volume resuscitation. Shock is poorly tolerated in elders because hemodynamic compensation is limited, and end-organ failure occurs earlier.

Certain injuries are more common and severe in elders. A subdural hematoma may occur after relatively trivial head trauma, and chronic subdural hematoma may be manifested as progressive dementia with only subtle neurologic findings. Increasing ankylosis of the spine, osteoarthritis, and decreased bone density as a result of osteoporosis render the geriatric cervical spine more susceptible to fracture. The elderly have more severe pulmonary contusions and a higher incidence of rib fractures and resultant complications (e.g., atelectasis and pneumonia) from preexisting pulmonary disease and a brittle thoracic wall. Skeletal fractures are more common, and lacerations and avulsions of atrophic skin are more difficult to repair and more prone to infection. This thin skin is also prone to decubitus breakdown in patients who are immobile, even for short periods, such as during spinal immobilization on an unpadded backboard.

PREVENTIVE CARE

Immunizations

Pneumonia, influenza, accidents, and adverse medical events are among the top seven causes of death in elders.[5] These conditions account for 15% of admissions and are potentially preventable. Annually, 36,000 adults die of complications from influenza and pneumococcal infections, and most of these deaths occur in elders. Immunization would reduce the incidence of clinical and serologic influenza by half in this population of patients. The Centers for Disease Control and Prevention (CDC) has a goal of an 80% immunization rate for patients in high-risk groups, including elders. The actual vaccination rate falls significantly below this goal. In patients 65 years old, 66% and 62% were vaccinated for influenza and pneumococcal disease, respectively, with the lowest rates among multiracial ethnic groups and people of lower socioeconomic means.[33] As a result, the CDC recommends that potential vaccination sites be extended to include walk-in clinics and EDs. Elders who have not been hospitalized or have not seen their primary care physician in the previous 3 years average at least one visit to an ED, and many are willing to be vaccinated there.

Despite this information, controversy exists about vaccination of elders in the ED. Emergency physicians can be reluctant to give vaccinations, citing time constraints and their concern about delivering primary care. Considering the low threshold in the ED for administration of the tetanus vaccine, it seems feasible that influenza and pneumococcal vaccination programs could be relatively easy and effective in the ED.

Falls

In combination with vaccinations, education about accident prevention in the home could have a considerable impact on the overall morbidity and mortality in elders. Falls and adverse medical events are the seventh leading cause of death in elders.[5] Whereas a primary care or social service provider may be a more appropriate source of information on fall prevention, the ED may be an additional resource to provide educational services to elders on a case-by-case basis, particularly in reference to any specific incident that prompted the need for emergency care. The leading cause of falls in elders is related to the use of pharmacologic agents, often prescription drugs.[30] Reviewing the patient's medications, searching for agents that might cause decreased cognition or dehydration, and addressing the need for these agents with the patient and the primary care provider could significantly decrease the risk for falls. In addition, informing the patient's primary care provider that the patient has fallen may facilitate education by the primary physician.

KEY CONCEPTS

- Polypharmacy and side effects of prescription and nonprescription drugs often occur in elders and should be considered in their evaluation.
- Physiologic changes that occur with aging make the clinical evaluation of elders difficult. Because of the difficulty in obtaining accurate histories and the often poor sensitivity of physical findings in elders with significant underlying disease, more diagnostic tests are generally obtained for these patients than for their younger counterparts who present with similar complaints.
- The immunosenescence that accompanies aging may blunt the fever response to infection and cause a less elevated white blood cell count.
- Myocardial infarction frequently presents atypically in elders as dyspnea, syncope, weakness, confusion, or abdominal complaints, often in the absence of accompanying chest pain.
- Abdominal pain in elders is often caused by surgical conditions that may require extensive evaluation in the ED, including radiographic studies.
- Elderly trauma patients have a higher morbidity and mortality than their younger counterparts because of exacerbation of underlying medical problems.

Section Four

THE PATIENT WITH COMPROMISED IMMUNE FUNCTION

CHAPTER 183

The Immunocompromised Patient

Michael J. Burns

PERSPECTIVE

As increased numbers of immunocompromised persons present to the emergency department (ED), it is essential that emergency physicians possess the knowledge and skills to recognize and to treat infectious complications of cancer, organ transplantation, diabetes, renal failure, cirrhosis, asplenism, human immunodeficiency virus (HIV) infection, and other immunosuppressive conditions. These include infectious complications of immunosuppressive and immunomodulating medications used for a wide variety of disorders.

Compared with individuals with an intact immune system, infections in immunocompromised patients are more common, progressive, and severe, and they are caused by a wider variety of microorganisms. Immunocompromised persons who present with acute infections may appear deceptively benign initially, their symptoms and signs often mimicking noninfectious complications, only to deteriorate rapidly if they are not aggressively treated. Many interrelated factors cause patients to become immunocompromised and predispose them to the development of infections with potentially pathogenic microorganisms. These include disruption of the body's protective surfaces, such as skin and mucosal barriers (oral and respiratory mucosa and intestinal and genitourinary surfaces); disorders that directly impair the function of the body's immune system (e.g., lymphoma, asplenism, and myeloma); drugs and irradiation that suppress or alter immune function; alterations in body substances (hyperglycemia) or solid organ function (kidney and liver failure); and malnutrition, aging, and exposure to antimicrobial agents that inhibit the normal protective resident bacterial flora.[1]

PRINCIPLES OF DISEASE

The body's defense mechanisms consist of surface barriers, such as skin, enzymes, and mucus, as well as innate (natural) and acquired (adaptive) responses. Innate responses occur to the same extent regardless of how often the body encounters the infectious agent, whereas acquired responses improve on repeated exposure.[2] Innate immunity is activated immediately on exposure to an infecting agent, rapidly controlling replication and allowing the requisite 3 to 5 days for the adaptive component to clone sufficient T and B cells to respond more specifically.[3-5]

Non–Microbe-Specific Immunity

Physical Barriers

The first line of defense against microorganisms consists of physical barriers. These include intact skin, gastrointestinal and respiratory mucosa, cilia, biofilm, gastric acid, antibacterial substances in pancreatic and biliary secretions, antimicrobial peptides and proteins on skin and mucous membranes, and resident microflora.[6]

In the respiratory tract, mucociliary transport and the cough reflex remove particulate matter and microbes, but this mechanism is impaired with smoking and ineffective cough. Mechanical ventilation or tracheostomy introduces large numbers of microbes that often overwhelm natural clearance.[7]

Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. Normal peristalsis and mucosal shedding help maintain normal gut flora. Alterations in these factors increase susceptibility to infection. Broad-spectrum antibiotics alter normal flora, permitting overgrowth of pathogens such as *Candida* species, multiantibiotic-resistant bacteria, and *Clostridium difficile*.

Initial Inflammatory Response and Innate Immunity

The first response to microbial invasion, the initial inflammatory response (formerly called the acute-phase response), acts to promote phagocytosis and microbial killing and to activate the immune system.[8] Sentry cells detect pathogens, immediately triggering inflammation. This innate immune response is not dependent on prior exposure to the pathogen. The initial inflammatory response factors, mainly produced in the liver, activate many cell types to synthesize and to release cytokines, chemokines, and "trigger molecules" that kill the invading organism.[3]

This response delivers humoral and cellular immune components to sites of inflammation and initiates antibody responses. Cytokines, platelet-activating factor, and hormone-like proteins, including interferons, are secreted from various immune cells and play important roles in mediation of this response.[9] These cytokines result in migration and adhesion of polymorphonuclear leukocytes and monocytes to sites of bacterial invasion. These cells release granules of substances that mediate vasodilation and increased vascular permeability, leading to edema, warmth, and redness, but also allow both phagocytic cells and humoral components to be concentrated at the site of infection.

A family of distinct transmembrane proteins, called Toll-like receptors, are found on many cell types, including macrophages, neutrophils, dendritic cells, mucosal epithelial cells, and endothelial cells. They recognize molecular patterns associated with microorganisms even in the absence of prior exposure, alert the host to the presence of the infectious agent and rapidly initiate a cascade of processes to activate innate immune responses, and help bridge innate and adaptive immune responses.[3,6]

www.ketabpezeshki.com 66485457-66963820

Reticuloendothelial System

The reticuloendothelial system, composed of tissue macrophages and their blood-borne counterparts, monocytes, removes particulate matter, including microbes, from the lymph and blood. The tissue component is concentrated in the lymph nodes, spleen, liver, marrow, and lung and has particular affinity for encapsulated bacteria such as pneumococci, meningococci, and *Haemophilus influenzae*. The vital importance of this non–microbe-specific system is demonstrated by the overwhelming sepsis from encapsulated organisms in patients with asplenia.

Adaptive (Microbe-Specific) Immunity

Humoral Immunity

Antibodies. Antibodies are produced by B lymphocytes, and each B cell produces a single microbe-specific antibody type. Stimulation by an antigen (or microbe) causes proliferation of this particular B cell so that large quantities of a specific circulating antibody can be produced. Furthermore, B cells are active in presenting antigens to T lymphocytes, which promotes cell-mediated immunity.

Immunoglobulins. IgM is the first immunoglobulin to appear in response to a new antigen. Although it has less affinity at binding antigens than IgG does, IgM provides some recognition of antigens and begins B-cell proliferation before the subsequent development of IgG.[10] IgM is detectable earlier in serum than IgG and serves as a marker for a patient's early response to acute infection.

Secretory IgA is the predominant immunoglobulin present in gastrointestinal fluids, nasal and oral secretions, tears, and other mucous fluids. IgA inhibits cell adherence of viral, bacterial, and protozoan pathogens and therefore prevents invasion by organisms through the respiratory or gastrointestinal tract.[10]

IgE, which is expressed in high concentration on the surface of mast cells and basophils, is responsible for immediate-type hypersensitivity responses. Mast cells and IgE are important in defense against helminthic pathogens.

IgG, which accounts for 75% of the total immunoglobulin mass, is widely distributed in tissues. It crosses the placenta and provides fetal immunity during the first 6 months of life. Congenital or acquired deficiencies of IgG lead to infection with encapsulated organisms because the predominant subtype (IgG2) has affinity for the dense polysaccharides of bacterial cell capsules, such as those of *Streptococcus pneumoniae* and *H. influenzae*.

Complement. The complement cascade, consisting of a complex interaction of 30 proteins, is another crucial component of humoral response. Complement is important in producing inflammation and leukocytosis and in recruiting leukocytes to sites of infection by production of chemoattractants. Complement also neutralizes viruses, enhances opsonization of bacteria, and produces bacterial cell wall and membrane lysis.

Both IgG and IgM, when they are in contact with an antigen, activate the classical pathway, whereas molecules with repeating chemical structures (e.g., bacterial cell walls and capsules) activate the cascade through the alternative pathway. Components of C3, the merging point of the classical and alternative paths, provide opsonization and modulate the response of lymphocytes (cell-mediated immunity). Opsonization is important in defense against infection with *S. pneumoniae, Streptococcus pyogenes, H. influenzae*, and *Staphylococcus aureus*. The terminal leg of the cascade, C5 through C9, forms the membrane attack complex, which inserts into cell walls and membranes and leads to cell death.

Individuals with inherited complement deficiencies are predisposed to frequent and recurrent infections with *S. pneumoniae, H. influenzae,* and especially *Neisseria meningitidis* and *Neisseria gonorrhoeae*.[11] The risk of meningococcal infection is increased several thousand-fold and most often develops in people deficient in C3 and in late complement components (C5-C8). Paradoxically, the disease is usually milder with complement deficiency, and mortality is likewise reduced fivefold to tenfold.[12] This suggests that the host response may be, in part, responsible for the severity of disease in normal individuals and is attenuated in complement deficiency. People with meningococcemia should be tested for inherited complement deficiencies because they may benefit from immunization.

Acquired deficiencies of complement function may develop in people with rheumatologic diseases, especially systemic lupus erythematosus (SLE). Approximately 40% of patients with SLE have an inhibitor of C5a-derived chemotaxis in their serum that results in enhanced susceptibility to infection.[13]

Cell-Mediated Immunity

Cell-mediated immunity (CMI) generally includes immune responses that are mediated by T lymphocytes, natural killer (NK) cells, and mononuclear phagocytes. CMI is vitally important in the control of infections caused by microbes that survive and replicate intracellularly, including most viruses and some bacterial (obligate and facultative intracellular types), fungal, and protozoan pathogens.

Only 5% of lymphocytes are in circulating blood. Most mature and are active in the marrow, thymus, spleen, and lymph nodes. The last two sites expose T cells to circulating antigen from invading microbes.[6] Specialized antigen-presenting cells in the lymphoid system sequester antigen and antigen-antibody complexes and present them to T cells. This process involves internalization and processing of the antigen, followed by formation of peptides that bind to a cell surface molecule called the major histocompatibility complex (MHC). Only with this specific presentation can a T lymphocyte become activated against a particular antigen.

Two major types of T lymphocytes are CD4 (helper cell) and CD8 (suppressor cell), corresponding to type II and type I of MHC, respectively. CD4 lymphocytes provide help for other cells in the immune system, including enhanced B-cell antibody production and production of cytokines. CD8 lymphocytes are generally cytotoxic and mediate the eradication of virally infected target cells and certain tumors. A decline in the number of CD4 cells, with predominance of CD8 cells, is responsible for the increased susceptibility to infection in patients with acquired immunodeficiency syndrome (AIDS).[6] Despite the cytotoxicity of CD8 cells, immunity is reduced without adequate numbers of CD4 cells.

Patients with defects in CMI are at increased risk for disseminated infection with intracellular bacteria, such as *Mycobacterium tuberculosis, Listeria monocytogenes,* and *Salmonella* species. The DNA viral infections, such as cytomegalovirus, herpes simplex, and varicella-zoster, also affect these patients more severely, as do fungal infections with *Candida, Cryptococcus, Mucor, Aspergillus,* and *Pneumocystis*. Finally, some protozoa are pathogenic without intact CMI, as infections with *Toxoplasma gondii* demonstrate.[14,15] Some infections are seen only below a certain CD4 cell count. *Pneumocystis* pneumonia is seen almost exclusively in patients with counts below 200 cells/mL (2×10^5 cells/L), whereas almost all patients with toxoplasmosis or cryptococcal meningitis have counts below 100 cells/mL (1×10^5 cells/L).

NK cells, closely related to lymphocytes but neither B nor T cells, are important in the innate immune response and are found in high concentrations in blood and spleen.[3,6] NK cells recognize infected cells and respond by directly killing these cells, and they secrete cytokines that activate macrophages to destroy phagocytosed microbes. These cells are important in defense against

www.ketabpezeshki.com 66485457-66963820

intracellular microbes, particularly viruses and intracellular bacteria such as *L. monocytogenes*.

Granulocytic Phagocytes

Granulocytic phagocytes are the cellular effectors of microbe killing, engulfing them and enzymatically lysing their cell membranes or walls. Two major types are polymorphonuclear leukocytes (also called neutrophils) and macrophages (the tissue version of circulating monocytes). Macrophages have surface receptors that recognize nonvertebrate carbohydrates such as mannose, which form the cell wall of some microorganisms. Hence, they can identify and attack "invaders" rather than "self."

Two other types of granulocytes, eosinophils and basophils, are less involved in the ingestion of organisms.[16] Eosinophils mediate the destruction of certain parasitic helminths through release of toxic proteins. Normally only 3% of total granulocytes, this cell type can reach 20% during times of high parasite load. Basophils (rare in circulation) and their tissue counterparts, mast cells, have high affinity for IgE. On exposure to antigens, they release granules with histamine, prostaglandins, and leukotrienes, which affect the allergic-inflammatory response with increased vascular permeability, bronchospasm, and vasodilation.[2]

Neutrophils constitute 90% of circulating granulocytes and spend only 6 to 8 hours of their average 4-day life in circulation (the remainder in tissues). Effective antibacterial activity depends on the ability of neutrophils to travel to sites of infection, a process known as chemotaxis. The locomotion of neutrophils along vascular endothelium is facilitated by adherence to cell surface proteins whose production is enhanced in the initial inflammatory response.[16]

Half of all neutrophils that leave the bone marrow circulate in the plasma. The other half become marginated, adhering to endothelium, primarily in the lungs, liver, and spleen. During periods of stress or with endogenous or exogenous catecholamines or corticosteroids, these neutrophils demarginate and enter the circulation. As long as the patient is not neutropenic, demargination causes an increased peripheral neutrophil count composed of mature cells, whereas with infection, an increased proportion of immature (band) forms is typically seen.

Neutrophils (and macrophages in tissue) bind to and ingest bacteria, a process called phagocytosis. This process is enhanced by proteins called opsonins that bind to bacterial surfaces. C-reactive protein, one of the initial inflammatory response proteins, fulfills this function for certain bacteria, including *S. pneumoniae*. IgG and complement protein C3b also opsonize bacteria, again illustrating the interdependence of the immune system. Actual killing takes place within granulocytes when cytoplasmic granules enzymatically produce potent oxidants. Granulocytes further control bacterial proliferation at the site of infection by elaborating lactoferrin, which locally binds free iron necessary for bacterial replication.

In addition to phagocytosis, macrophages (located in the spleen, alveoli, liver, and lymph nodes) modulate the immune response by presenting antigens to lymphocytes and releasing cytokines and complement components. Activation of macrophages to ingest bacteria depends on interaction with interferon-γ, a cytokine manufactured by T cells.[6] Thus the once clear demarcation between cellular and humoral immunity is breaking down as more is understood about the interdependent immune system.

SPECIFIC IMMUNOCOMPROMISED STATES

Solid Organ Transplants

See Chapter 184.

Cancer

Patients with cancer frequently have multiple immune defects, such as neutropenia and impaired function of T and B cells, induced by cancer chemotherapy or by the disease process itself, which predisposes them to infection. Other factors leading to infection are defects in physical barriers (skin and mucous membranes), including cytotoxic effects of chemotherapy on cells lining the gastrointestinal tract. In addition, splenic dysfunction or splenectomy, use of long-term intravascular catheters, frequent use of complex invasive diagnostic and therapeutic procedures, toxic effects of radiation therapy, and frequent colonization with antimicrobial-resistant pathogens are predisposing factors. Cancer treatments (e.g., allogeneic bone marrow and autologous stem cell transplantation, platelet transfusion, granulocyte colony-stimulating factor, and implanted central venous catheters) increase survival during episodes of profound immunosuppression, allowing patients to receive more intense cytotoxic cancer chemotherapy regimens. This results in long survival of patients with neoplastic diseases that were formerly rapidly fatal. Despite many advances in supportive care, infections continue to result in serious morbidity and mortality. Furthermore, increasing resistance to antimicrobials is occurring among common pathogens along with the emergence of new opportunistic pathogens. Infection is much more common in patients with acute leukemia and lymphoma (75% of patients) and multiple myeloma (50% of patients) than in those with solid tumors.[17] Factors predisposing to infection in immunocompromised patients are listed in Box 183-1.

Neutropenia

Principles of Disease. Neutropenia is defined as a neutrophil count of less than 500 cells/mL (5×10^5 cells/L), including band forms, or less than 1000 cells/mL (1×10^6 cells/L) and expected to fall to less than 500 cells/mL.[18,19] It usually results from cytotoxic chemotherapy or radiation therapy or the disease process, especially in hematologic malignant neoplasms. In addition, cancer chemotherapeutic agents and radiation therapy can cause functional defects in granulocytes. The risk of febrile neutropenia and mortality is higher in the first one or two cycles of multicycle cytotoxic chemotherapy regimens.[20]

The incidence and severity of infection in cancer patients with neutropenia are inversely proportional to the absolute neutrophil count and directly proportional to the duration of neutropenia. Although the incidence begins to rise as the neutrophil count falls below 500 cells/mL (5×10^5 cells/L), most severe infections and almost all bacteremias occur when the neutrophil count is less than 100 cells/mL.[21] Fever in the neutropenic patient is defined as a single temperature of 38.3° C (101° F) or higher or a temperature of 38.0° C (100.4° F) or higher during 1 or 2 hours.[19] In neutropenic patients, the temperature should be measured orally or tympanically, not rectally. Although fever can be suppressed or lessened by immunosuppressive agents such as corticosteroids and nonsteroidal anti-inflammatory drugs, most cancer patients with infection manifest fever despite the use of these agents.[22] Also, although it is uncommon, immunocompromised patients can have serious local or systemic infections without fever. This is manifested by unexplained tachypnea or tachycardia, mental status changes, metabolic acidosis, increased volume requirements, rapid changes in serum glucose or sodium concentration, or acute abdominal pain. Because the onset of life-threatening infections can be rapid in cancer patients with severe neutropenia or a history of splenectomy, urgent evaluation and initiation of antimicrobial therapy are essential. A prospective multicenter observational study of febrile neutropenic cancer patients in EDs in France found that critically ill patients were poorly recognized and undertreated,

Haemophilus influenzae

low-risk patients were overtreated, and compliance with established guidelines was low.[23]

The most common sites of infection in neutropenic patients are the lung (25%); mouth and pharynx (25%); gastrointestinal tract (15%); skin, soft tissue, and intravascular catheters (15%); perineum and anorectal area (10%); urinary tract (5%); and nose and sinuses (5%).[24] Pneumonia and anorectal infection are more likely to be associated with bacteremia. Bacteremia may occur without an obvious source despite intensive investigation. Historically, the most important bacteria are three gram-negative bacilli—*Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*—and four gram-positive cocci—*Staphylococcus epidermidis*, viridans group streptococci, *Enterococcus* species, and *S. aureus*. Many centers that treat large numbers of cancer patients note a decrease in these gram-negative bacilli and an increase in infections caused by others, such as *Enterobacter*, *Citrobacter*, and *Serratia* species, which are capable of rapidly developing resistance to cephalosporins and extended-spectrum penicillins. Anaerobes are uncommon but may be important in certain mixed infections (e.g., mouth, abdominal, and perianal).

During the past 25 years, infection with gram-positive organisms (e.g., coagulase-negative staphylococci, *S. aureus*, viridans streptococci, and *Enterococcus* species) has increased, and this is now the leading cause of bacterial infection (50-70% at some centers) in febrile neutropenic cancer patients in the United States, Canada, and western Europe. Gram-negative organisms still predominate in developing countries.[25,26] With the exception of viridans streptococci, most of these gram-positive organisms do not produce immediately life-threatening infections compared with the rapid lethality of many gram-negative infections. Life-threatening bloodstream infections caused by viridans streptococci (especially *Streptococcus mitis*) are common in many cancer centers and often respond poorly to penicillins and cephalosporins. Risk factors for serious viridans streptococcal infections include aggressive cytoreduction therapy for acute leukemia or allogeneic bone marrow transplantation (especially after high-dose cytosine arabinoside treatment), profound neutropenia, and severe oral mucositis. Other factors include prophylactic use of trimethoprim-sulfamethoxazole or fluoroquinolones, use of antacids or H_2 receptor antagonists, and childhood.[27,28]

Aspergillus and *Candida* species are the most common fungi producing infection in cancer patients with fever and neutropenia.[24,29,30] Infection is most likely to develop in neutropenic patients treated with broad-spectrum antimicrobials and in those whose fever persists for more than 7 days. *Aspergillus* species usually produce necrotizing infections in the lung or sinuses. Pulmonary aspergillosis often is manifested with pleuritic pain, hemoptysis, and localized wheezing. The chest radiograph demonstrates

www.ketabpezeshki.com 66485457-66963820

pleural effusion or focal infiltrates. Computed tomography (CT) is more sensitive in detection of pulmonary infiltrates compatible with aspergillosis, and it may demonstrate a distinct halo of low attenuation surrounding a pulmonary infiltrate. This pattern is highly suggestive of invasive aspergillosis, although mucormycosis and other disorders may mimic the halo. Invasive aspergillosis originating in the paranasal sinuses may extend to the surrounding bone and brain. Often, an initial red-purple lesion on the nasal turbinate or palate turns pale and then black as vascular invasion produces infarction of the mucosa and bone. The black eschar on the nose or palate is easily misdiagnosed as dried blood. Patients presenting with head or facial pain or swelling, or proptosis, should be rapidly evaluated for invasive aspergillosis and mucormycosis. *Candida* species produce infections of the skin, oral cavity, and esophagus as well as fungemia. The sudden onset of generalized rash consisting of pink-purple, nontender subcutaneous nodules is characteristic of candidemia.

Less common fungi producing infection in these patients include *Mucor* and *Rhizopus* species (necrotizing pneumonia and sinusitis), *Trichosporon* species (pneumonia and fungemia), and *Pseudallescheria boydii* (soft tissue infection). Other than *Candida* species, these fungi are rarely found in blood cultures. Specific diagnosis requires biopsy.

Clinical Features. Certain clinical findings are characteristic of specific pathogens (Table 183-1). Noninfectious causes of fever also need to be considered, such as drug toxicity, drug allergy, transfusion reactions, and pulmonary emboli.[17] Fever is frequently the only sign of infection because these patients are unable to mount a full inflammatory response at a site of infection.[24] Usual symptoms and signs of infection may not be present, especially when the neutrophil count is less than 100 cells/mL (1×10^5 cells/L). When pneumonia develops, purulent sputum may be absent, and the initial chest radiograph may not show an infiltrate. Pyuria may be absent in the presence of urinary tract infection. Areas of cellulitis may have diminished or absent induration and redness and no purulent drainage. Tenderness may be the only finding in perineal and anal infections. The neutropenic patient with a documented infectious cause of fever may be difficult to distinguish from the patient with fever not caused by infection. The performance of a procedure before the onset of fever, presence of chills, "toxic appearance," and lack of localized findings do not help determine whether the patient is bacteremic.[31] Only 20% of febrile neutropenic patients have a clinical focus of infection identified at presentation, and only 30% of patients have positive blood cultures.

Table 183-1 Characteristic Clinical Findings in Neutropenia That May Be Associated with Infection with Specific Pathogens

CHARACTERISTIC CLINICAL FINDINGS	SUSPECT PATHOGENS
Ulcerative lesions in the mouth	Viridans streptococci, herpes simplex, *Candida*, anaerobes
Necrotizing skin lesions	*Pseudomonas aeruginosa, Aeromonas hydrophila, Aspergillus, Mucor*
Nontender subcutaneous nodules	*Nocardia, Cryptococcus*
Nontender pink skin papules	*Candida*
Black eschar of nose or palate	*Aspergillus, Mucor*
Generalized macular red rash	Viridans streptococci
Right lower quadrant abdominal pain, tenderness, distention, bloody diarrhea	Typhlitis (neutropenic enterocolitis) caused by *Pseudomonas aeruginosa, Escherichia coli, Clostridium septicum*
Perineal pain and tenderness without inflammation or abscess	Gram-negative bacilli, anaerobes
Redness or pain at vascular catheter sites	Coagulase-negative staphylococci, *Corynebacterium, Bacillus* species

Mucositis involving the mouth and other mucous membranes is a painful and debilitating condition that commonly occurs in cancer patients receiving intense chemotherapy. It is a frequent prelude to viridans streptococcal bacteremia, which can produce sudden onset of acute respiratory distress syndrome, a toxic shock–like syndrome, rash, and pneumonia.

Diagnostic Strategies. The evaluation of the cancer patient with fever and neutropenia should include a meticulous search for subtle symptoms and signs of inflammation at common sites: oral cavity and pharynx, lower esophagus, lung, skin, perineum including anus, bone marrow aspiration sites, vascular catheter sites, and tissue around the nails.[21] In nearly two thirds of patients, the initial evaluation does not identify a focus of infection.[22] Two sets of blood culture specimens should be obtained. If the patient has a central venous catheter, culture specimens of blood should be obtained from each lumen of a multilumen catheter and from at least one peripheral site.[19] Specimens for culture should also be obtained from any site of inflammation, including inflamed or draining catheter exit sites. Patients with severe mucositis should have herpes simplex cultures performed if they are not receiving antiherpes prophylaxis, and they should have a smear for *Candida* pseudohyphae. Complete blood count, electrolyte values, transaminase levels, blood urea nitrogen concentration, and creatinine concentration should be determined to plan management and to monitor the occurrence of drug toxicity.

Urine culture should be performed if symptoms or signs of a urinary tract infection are present, if a urinary catheter is in place, or if the urinalysis is abnormal. Examination of the cerebrospinal fluid is not recommended as a routine procedure unless subtle symptoms or signs of meningitis are present.

A chest radiograph should be obtained in patients with respiratory symptoms and signs.[19] If the chest radiograph is normal or inconclusive but there is still suspicion for pneumonia, high-resolution CT or thin-section multislice CT scanning of the chest without contrast enhancement should be obtained because pneumonia is often detected by chest CT in febrile neutropenic patients with normal findings on the chest radiograph.[32] CT evaluation of the sinuses should be performed if facial pain or swelling is present. In patients with abdominal pain and tenderness, CT scanning of the abdomen is useful for diagnosis of neutropenic enterocolitis ("typhlitis"), a necrotizing infection of the bowel wall that usually affects the cecum. This is more commonly seen in acute leukemia and is not generally treated surgically. Ultrasonography over a subcutaneous tunneled catheter track and its vein of insertion may reveal the presence of an abscess or infected thrombus.[33]

In patients with diarrhea, stool testing for *C. difficile* toxin as well as culture for routine bacterial pathogens should be obtained. *C. difficile* colitis occasionally produces abdominal pain in the absence of diarrhea. *Cryptosporidium parvum,* a protozoan, may cause profuse, watery diarrhea and is detected by acid-fast staining or immunofluorescence testing of stool.

Management of Febrile Neutropenia

Antibiotic Therapy. Broad-spectrum antimicrobial therapy should be initiated promptly in the febrile neutropenic patient if the neutrophil count is less than 500 cells/mL (5×10^5 cells/L) or if the neutrophil count is 500 to 1000 cells/mL (5 to 10×10^5 cells/L) and expected to drop.[19,34] Moreover, even afebrile neutropenic patients who have symptoms and signs (e.g., abdominal pain and tenderness) compatible with an infection should be treated empirically (Table 183-2).

Use of a single antimicrobial agent is preferred in most patients because there is no conclusive evidence of a benefit from multiple drugs.[19,35,36] Factors that should be considered in choosing an antimicrobial agent include renal and hepatic function, drug allergies,

www.ketabpezeshki.com 66485457-66963820

Table 183-2 Selected Antimicrobial Agents Useful in the Immunocompromised Patient

DRUG	DOSAGE: Adult	DOSAGE: Child (age > 28 days)	PRECAUTIONS AND COMMENTS
Aminoglycosides			
Gentamicin	2 mg/kg loading dose, then 5 mg/kg/day IV q8-12h, *or* 5-7 mg/kg IV once daily	Same as adult	Decrease maintenance dose in elderly or with renal dysfunction.
Tobramycin	Same as gentamicin	Same as adult	
Amikacin	10 mg/kg/day loading dose, then 15 mg/kg/day IV q12h or once daily	Same as adult	
Extended-Spectrum Penicillins and β-Lactamase Inhibitors			
Piperacillin-tazobactam	4.5 g IV q6h	240-400 mg/kg/day IV q6h	For *Pseudomonas aeruginosa*, administer with aminoglycoside.
Cephalosporins			
Ceftazidime Cefepime	1-2 g IV q6-8h 1-2 g IV q8h	150 mg/kg/day IV q8h 150 mg/kg/day IV q8h	Both are active against *P. aeruginosa,* but cefepime is more active than ceftazidime against gram-positive organisms and some resistant gram-negative bacilli.
Carbapenems			
Imipenem-cilastatin	0.5-1 g IV q6h	60-100 mg/kg/day IV q6h	Adjust dose in elderly or with renal dysfunction.
Meropenem	0.5-1 g IV q8h	60-120 mg/kg/day IV qh8	Seizures are associated with imipenem. May be cross-allergenic with penicillin Broad-spectrum activity against gram-positive and gram-negative organisms, including *P. aeruginosa* and anaerobes
Other			
Aztreonam	1-2 g IV q8h	120 mg/kg/day IV q6h	Active against gram-negative bacilli including *P. aeruginosa* Not active against gram-positive organisms Safe in penicillin-allergic patient
Vancomycin	15 mg/kg IV q12h	40 mg/kg/day IV q6-12h	Infuse during 2 hours (flushing, hypotension with rapid infusion).
Amphotericin B	0.5-1.5 mg/kg/day IV once daily	Same as adult	Refer to infectious disease or pharmacology text.
Acyclovir			Infuse during 1 hour.
Herpes simplex, mucocutaneous*	5 mg/kg IV q8h *or* 400 mg PO three times a day	250 mg/m^2 IV q8h *or* 15 mg/kg/day PO q4h	
Herpes zoster			
Not severe†	800 mg PO five times a day	20 mg/kg PO four times a day	
Severe	10 mg/kg IV q8h	500 mg/m^2 IV q8h	Elderly: 7.5 mg/kg IV q8h
Primary varicella	10 mg/kg IV q8h	500 mg/m^2 IV q8h	

*Alternative for herpes simplex: famciclovir 250 mg three times a day, or valacyclovir 1 g two times a day PO.
†Alternative for herpes zoster: famciclovir 500 mg three times a day, or valacyclovir 1 g three times a day PO q8-12h.

suspected site of infection or organism, and cost. Antimicrobial resistance varies widely, and in the absence of a written hospital-specific protocol, immediate consultation with an oncologist or an infectious diseases specialist may be of great assistance.

Monotherapy with intravenous cefepime, ceftazidime, imipenem, meropenem, or piperacillin-tazobactam is preferred, with an aminoglycoside (gentamicin, tobramycin, or amikacin) added for the more seriously ill patient.[19,24,37,38] Monotherapy, without an aminoglycoside, may be advantageous in the patient with mild to moderate renal dysfunction or for patients receiving nephrotoxic agents, such as cisplatin, cyclosporine, or amphotericin B. Ceftazidime-resistant gram-negative bacilli are common pathogens at some centers. In addition, ceftazidime is the least active against gram-positive organisms, compared with cefepime, cefotaxime, or ceftriaxone. Cefepime, a broad-spectrum cephalosporin with excellent activity against both gram-positive and gram-negative organisms, including *P. aeruginosa,* is preferred at many centers. The carbapenems imipenem and meropenem provide excellent activity against gram-negative organisms (including *P. aeruginosa*), gram-positive organisms, and anaerobic bacteria. None of the antimicrobial agents previously listed is active against vancomycin-resistant *Enterococcus* species or methicillin-resistant staphylococci.

For patients who are allergic to β-lactam antibiotics (e.g., penicillins, cephalosporins, imipenem, and meropenem), coverage of gram-negative bacilli, including *P. aeruginosa,* can be provided by aztreonam. Because aztreonam is not active against gram-positive or anaerobic bacteria, it should be combined with an antimicrobial such as vancomycin. If anaerobes are suspected (i.e., oral, abdominal, or perianal infection) in the β-lactam–allergic patient or in the patient receiving cephalosporin monotherapy, an anti-anaerobic drug such as clindamycin or metronidazole should be

www.ketabpezeshki.com 66485457-66963820

administered. Empirical treatment with intravenous fluoroquinolones is not recommended in the febrile neutropenic cancer patient because of frequent prophylactic use of these agents in the cancer patient, risk for rapid emergence of resistance in gram-negative bacilli, and predisposition to *C. difficile* infection.[19,39,40]

When a focus of infection is identified, empirical therapy should cover the most likely pathogens causing infections at the site. For example, patients with pneumonia may need coverage for *Legionella* (fluoroquinolone, azithromycin, doxycycline, or erythromycin), *Pneumocystis* (trimethoprim-sulfamethoxazole), or fungi (amphotericin B) in addition to standard antibacterial coverage. Agents effective against anaerobes (clindamycin, metronidazole, imipenem, meropenem, and piperacillin-tazobactam) should be considered for patients with perianal or oral infection and those with abdominal pain, who may have appendicitis, diverticulitis, or typhlitis (neutropenic enterocolitis). Acyclovir should be considered for patients with ulcerative or vesicular lesions who may have herpes simplex or varicella-zoster virus infections. Ganciclovir may be required for treatment of cytomegalovirus infection, which is rare in febrile neutropenic cancer patients. Foscarnet may be needed for acyclovir-resistant herpes simplex or ganciclovir-resistant cytomegalovirus infections. In patients with severe mucositis and febrile neutropenia, a carbapenem or extended-spectrum penicillin is preferred for empirical treatment rather than a higher generation cephalosporin because of superior efficacy against viridans streptococci.

Routine empirical use of vancomycin for the febrile neutropenic cancer patient is not recommended because of concern about the development of vancomycin-resistant organisms.[19,27,41,42] Randomized clinical trials show no survival advantage when vancomycin is in the initial therapy for all neutropenic patients, even those with indwelling catheters. Because most infections with gram-positive bacteria are indolent, vancomycin therapy can be safely delayed for 24 to 48 hours in most patients until a vancomycin-requiring gram-positive infection is identified.[43]

Indications for initial empirical vancomycin therapy include serious catheter-related infections, known colonization with penicillin-resistant pneumococci or methicillin-resistant *S. aureus,* and positive blood culture for gram-positive organisms before final identification and susceptibility testing. Other indications include shock; severe mucositis; prior fluoroquinolone prophylaxis; and institutions in which methicillin-resistant *S. aureus,* vancomycin-susceptible enterococci, and *S. mitis* are frequent pathogens.

Patients previously colonized or infected with methicillin-resistant *S. aureus,* vancomycin-resistant enterococci, extended-spectrum β-lactamase–producing gram-negative bacteria, and carbapenemase-producing organisms may require modifications to initial empirical therapy.[19]

Amphotericin B (and its lipid formulations) is the drug of choice for treatment of invasive fungal infections in patients with neutropenia.[19,41,44] Up to one third of febrile neutropenic patients not responding to 1 week of antibiotics have systemic fungal infections, usually *Candida* or *Aspergillus*. Antifungal agents, such as caspofungin, voriconazole, or posaconazole, may be indicated in selected cases. Empirical use of fluconazole is not recommended because of lack of activity against *Aspergillus* and some *Candida* species.

Cell Stimulation Therapy

For prevention and treatment of neutropenia, some centers routinely use human recombinant hematopoietic or colony-stimulating growth factors (granulocyte colony-stimulating factor: filgrastim, pegfilgrastim; granulocyte-macrophage colony-stimulating factor: sargramostim) to stimulate the proliferation and maturation of bone marrow progenitor cells and to increase the number and function of these committed cell populations. Although they are safe and well tolerated, they are very expensive. Treatment with these agents after chemotherapy may shorten the hospital stay and the duration of fever, but no good evidence exists that they prolong survival or affect the frequency of severe infections. Many authorities recommend that use of these agents should be limited to high-risk neutropenic patients, such as elders and those with severe sepsis, multiorgan failure, or recurrent febrile neutropenia.[19,45,46]

Risk Assessment for the Patient with Febrile Neutropenia, Including the Concept of Brief Observation and Early Discharge of the Low-Risk Patient

Febrile neutropenic cancer patients can be classified into high-risk and low-risk groups.[19,47-49] Factors associated with high-risk patients include the following: status as inpatient when fever and neutropenia develop; presence of comorbid medical conditions; uncontrolled cancer; acute leukemia; hemodynamically unstable; evidence of organ failure; presence of pneumonia, severe soft tissue infection, infection of a central line, abdominal pain, or neurologic or mental status abnormalities; and neutropenia expected to last more than 10 days. These patients should be treated in the hospital with intravenous antibiotics.

Low-risk patients generally have an excellent outcome with therapy and are clinically stable outpatients with solid tumors, lymphomas, or chronic leukemia who lack any of the high-risk factors noted previously and who are not receiving fluoroquinolone prophylaxis. Low-risk patients with fever and neutropenia may be treated in the hospital with oral antibiotics, such as ciprofloxacin plus amoxicillin-clavulanate (or ciprofloxacin plus clindamycin in penicillin-allergic patients).[47-49] Furthermore, oral antibiotic therapy with early discharge is safe and effective in carefully selected low-risk patients.[19,49-52] Hospitalization exposes low-risk patients to potential iatrogenic complications and antimicrobial-resistant nosocomial pathogens, and early discharge followed by outpatient treatment allows an improved quality of life.

Low-risk patients may be hospitalized initially, stabilized during 12 to 48 hours, and then discharged to continue parenteral or oral antibiotics. Some authorities recommend a period of observation less than 12 hours, which may allow discharge from the ED, an observation unit, or physician's office.[49] The patient should be observed for at least 2 hours after administration of the first dose of antibiotics and discharged only after consultation with the patient's oncologist. Patients sent home need adequate instructions, family support, and easy access to a hospital in case of emergency.[49-57] The 2011 clinical practice guidelines of the Infectious Diseases Society of America and the National Comprehensive Cancer Network support outpatient or short-stay oral antibiotic therapy in carefully selected low-risk patients with neutropenic fever.[19,49]

Non-Neutropenic Conditions in the Cancer Patient

The Solid Cancer Patient without Neutropenia. Most solid cancer patients who have fever and infection are not neutropenic. Infections often occur after surgical procedures and may include wound infection, deep abscess, or perforated viscus. Infections may be associated with central venous or urinary catheters, stents, and prosthetic devices. In addition, solid tumor patients with large tumor lesions may have obstructive infections (of bronchus, bile duct, or ureter). The spectrum of microorganisms includes a wide variety of indigenous organisms (bacterial, fungal, and viral) as well as nosocomial multiantibiotic-resistant pathogens.

Prompt initiation of antimicrobial therapy in the febrile non-neutropenic solid cancer patient is not always indicated. Rapid surgical intervention may be more important than

www.ketabpezeshki.com 66485457-66963820

the urgent initiation of empirical antibiotics. In febrile non-neutropenic cancer patients who are not ill-appearing and have no identified focus of infection, it may be appropriate to obtain culture specimens and to observe the patient. After consultation with an oncologist, some patients can be discharged home with close follow-up. Indications for urgent antibiotics include signs of sepsis, mental status changes, lactic acidosis, shock, abdominal pain, history of splenectomy, and identification of a focal site of infection.[58,59]

Impaired Cell-Mediated Immunity. The T-cell defects resulting from impaired CMI in cancer patients usually result from cancer chemotherapy or corticosteroid treatment. The cancer impairs CMI in patients with Hodgkin's disease, non-Hodgkin's lymphoma, and hairy cell leukemia.

Bacterial Infections. *Listeria monocytogenes* is one of the more common bacterial organisms infecting cancer patients with impaired CMI.[60-63] *Listeria* infection is also seen in patients with organ transplants, diabetes, cirrhosis, and AIDS and in those receiving high-dose corticosteroids. No early characteristics distinguish *Listeria* infection from bacteremias caused by other organisms. Meningitis, which may be accompanied by cerebritis or brain abscess, is the most common focus of infection and may be manifested with personality changes or focal neurologic signs.[64] Cerebrospinal fluid examination frequently does not reveal the organism on Gram's stain, but protein is elevated and pleocytosis is present. Treatment should be with ampicillin and gentamicin. Trimethoprim-sulfamethoxazole is the alternative drug for patients with penicillin allergy. Vancomycin is not effective in treatment of *Listeria* infections even when in vitro susceptibility is shown. Cephalosporins, such as ceftriaxone and cefotaxime, are not active against *Listeria*.

Infections caused by *Salmonella* species are common in patients with impaired CMI and usually are manifested with fever with or without enteritis.[65] Bacteremia can result in infection of bones, joints, central nervous system, and endovascular devices. Multidrug-resistant *Salmonella* species are increasing. Treatment usually includes a third-generation cephalosporin or a fluoroquinolone because many isolates are resistant to ampicillin and trimethoprim-sulfamethoxazole.[66]

Patients with solid tumors, lymphoma, and leukemia (especially hairy cell leukemia) are at increased risk for pneumonia from *Legionella* species, with the highest risk in cancer patients receiving high-dose corticosteroids.[67,68] Non-*pneumophila* species of *Legionella* (e.g., *Legionella micdadei* and *Legionella bozemanii*) are particularly common in these patients.[69] Clinical and radiographic manifestations of *Legionella* infection in the immunocompromised patient often differ from those in the immunocompetent host. For example, pleuritic chest pain may be a prominent symptom in the immunocompromised patient and may mimic pulmonary embolism. These patients can have fever without any other symptoms of pneumonia despite the presence of radiographic pulmonary infiltrates. In addition, the chest radiograph may reveal an expanding pulmonary nodule or cavitation of a nodule or infiltrate rather than the usual lower lobe alveolar filling defects. Hyponatremia (serum sodium <130 mEq/L [mmol/L]) is particularly common. Although gastrointestinal and neurologic symptoms and elevated serum transaminase levels are common in patients with *Legionella* infections, these are not more common in patients with *Legionella* than in those with other causes of pneumonia. The treatment of choice for immunocompromised patients with *Legionella* infection is a fluoroquinolone or azithromycin (alternatively, doxycycline or erythromycin, each combined with rifampin).

Nocardiosis is an uncommon but often severe bacterial infection caused by a weakly acid-fast gram-positive branching filamentous rod. It occurs in cancer patients, in those receiving high-dose corticosteroids, and in others with defective CMI.[70,71] Subacute pneumonia with nodular infiltrates is the most common manifestation, but *Nocardia* may also produce cellulitis, subcutaneous abscesses, meningitis, and brain abscess. Diagnosis requires biopsy, tissue stains, and culture. Treatment is with sulfonamides often combined with other agents.

Mycobacterial Infections. Tuberculosis and other mycobacterial diseases may produce severe disease in those with defective CMI and be manifested as fever of undetermined origin, pneumonia, lymphadenopathy, or skin lesions.[72,73] It is easily mistaken for signs caused by the patient's underlying disease or treatment. Disseminated nontuberculous mycobacterial infections are more common in patients with hairy cell leukemia or chronic myelogenous leukemia.

Fungal Infections. Infections with *Cryptococcus neoformans* and *Cryptococcus gattii* occur in patients with Hodgkin's and non-Hodgkin's lymphoma, chronic myelogenous leukemia, and chronic lymphocytic leukemia, especially those taking high-dose corticosteroids.[74] Patients with HIV infection, solid organ transplants, diabetes, renal insufficiency, and cirrhosis are also at risk, as are patients receiving prolonged high-dose corticosteroids for connective tissue diseases. Meningitis is the most common manifestation, often with the insidious onset of low-grade fever and subacute (and often intermittent) headache. Many other organ systems can become infected, including the lung, skin, bones, and joints. Diagnosis is made by measurement of cryptococcal antigen (*not antibody*) in serum and cerebrospinal fluid and by fungal cultures and tissue biopsy.[75]

Impaired CMI may result in reactivation of *Histoplasma capsulatum* and *Coccidioides immitis* with resultant disseminated disease. Infections with *Candida* species are also common in cancer patients with defective CMI, but disseminated disease is less likely than in patients with neutropenia. Invasive aspergillosis may develop in cancer patients receiving high-dose corticosteroids but not as commonly as in those with organ transplants or prolonged neutropenia. *Pneumocystis jiroveci* (formerly *carinii*) pneumonia is most common in patients with AIDS, leukemia, and lymphoma and in patients with solid tumors taking high doses of corticosteroids.

Parasitic Infections. Reactivation of central nervous system infection with the protozoan *T. gondii* occurs most often in cancer patients with lymphoma and leukemia as well as in HIV infection. *Strongyloides stercoralis,* an intestinal nematode, is the only helminthic organism producing severe infection in patients with deficient CMI, almost exclusively in those receiving high-dose corticosteroids.[76,77] Larvae of the parasite disseminate from intestine to the lung and other organs, including the central nervous system and skin. Wheezing, cough, dyspnea, hemoptysis, and rash are common symptoms. Chest radiographs may show focal or diffuse infiltrates. Dissemination is often accompanied by bacterial infection, usually caused by enteric gram-negative bacilli carried by the parasites from the intestinal tract. Diagnosis includes examination of sputum and stool for parasites. Treatment of choice is ivermectin; thiabendazole is a less effective alternative.

Viral Infections. The most common viruses producing serious infections in cancer patients with defective CMI are varicella-zoster, herpes simplex, and cytomegalovirus.[78] Visceral dissemination is common in primary varicella in nonimmune immunocompromised children and adults. When a nonimmune immunocompromised child or adult is exposed to varicella, varicella-zoster immune globulin (VariZIG, approved by the Food and Drug Administration in the United States for this indication) can be given within 96 hours of exposure to ameliorate the disease.[79] Herpes zoster infection is common in cancer patients, particularly those with Hodgkin's and non-Hodgkin's lymphoma and leukemia. Disease usually remains localized to the primary dermatome, but dissemination occurs in approximately 11% of patients. Dissemination is usually limited to the skin, but visceral

www.ketabpezeshki.com 66485457-66963820

involvement (lung and liver) occasionally occurs. Skin lesions in primary varicella or zoster often become hemorrhagic in these patients.

Reactivation of herpes simplex virus is common, resulting in severe mucocutaneous infection in oral or genital areas. Spread may occur to the esophagus, lungs, or other organs. Herpetic lesions in cancer patients tend to be larger and deeper than those in the immunocompetent patient. Acyclovir given intravenously is the treatment of choice for varicella-zoster and herpes simplex infections in immunocompromised patients, but some authorities recommend oral famciclovir or valacyclovir for stable patients.

Cytomegalovirus infection may occur in cancer patients treated with corticosteroids. Measles virus, although uncommon, may produce severe infection with defective CMI. Fever, rash, pneumonia, and encephalitis are common manifestations. Immune serum globulin may be given after exposure to ameliorate disease. Common community respiratory viruses, such as respiratory syncytial virus, influenza, and adenovirus, may produce severe or fatal pneumonia.[80]

Humoral Immune (B-Cell) Defects. Hypogammaglobulinemia is common in patients with chronic lymphocytic leukemia and myeloma. Low immunoglobulin levels predispose to infections with encapsulated bacteria, such as *S. pneumoniae, H. influenzae,* and *N. meningitidis*.[81-84] Pneumonia is the most common manifestation, but sepsis, otitis media, cellulitis, and urinary tract infection may occur. After receiving cytotoxic agents and corticosteroids for treatment, these patients become susceptible to infections associated with impaired CMI as well as bacterial infections caused by *S. aureus* and gram-negative bacilli. Regular infusions of intravenous immune globulin may decrease the incidence of infection but do not prolong survival. Patients should receive pneumococcal vaccine, but many do not respond.

Disruption of Natural Barriers. Disruption of natural anatomic barriers (e.g., mucous membranes and skin) by ulcerating tumors, chemotherapy, radiation therapy, diagnostic and therapeutic procedures, and catheters can lead to infection by gram-positive and gram-negative organisms, including anaerobes.[85] Oral mucositis, a debilitating and intensely painful condition associated with radiation therapy and high-dose chemotherapy, frequently results in serious local and systemic infections, including life-threatening sepsis with viridans streptococci.[86,87] Cancers may cause partial or total obstruction of body lumens and cavities. Stenosis of a lumen may result from radiation therapy. Bronchial obstruction by tumor can lead to pneumonia. Obstruction of the urinary tract may result in infection. Gastrointestinal tract obstruction can lead to perforation and peritonitis.

Opportunistic Infections Mimicking Neoplasm. Infectious agents can produce laboratory, radiologic, or physical findings that resemble those caused by the spread of tumor. For example, mass lesions in the brain caused by *Nocardia* or *Toxoplasma* can be mistaken for cancer metastases. *Aspergillus, Mucor, Rhizopus,* and related fungi invade blood vessel walls and produce thrombosis, which may result in Budd-Chiari syndrome (hepatic vein obstruction), nephrotic syndrome, or oculomotor palsy that may be misattributed to the spread of tumor. Renal vein thrombosis can be caused by infection with gram-negative bacilli. *Candida* fungus balls may develop in one or both ureters, producing a picture of postrenal obstructive uropathy. *Histoplasma, Pneumocystis, Legionella, Aspergillus, Nocardia,* and other organisms can produce pulmonary nodules and be mistaken for pulmonary metastases.

Pulmonary Infections in the Immunocompromised Patient. In neutropenic cancer patients, pneumonia is commonly caused by gram-negative bacilli early in neutropenia and by fungal organisms such as *Aspergillus* late. In those with impaired CMI, cytomegalovirus, *Pneumocystis, Legionella, Nocardia,* mycobacteria, and fungal organisms predominate. Pneumococcal pneumonia is most common in patients with impaired humoral immunity. Patients with primary lung cancer or with pulmonary metastases from other cancers develop postobstructive pneumonia, lung abscess, and empyema related to *S. aureus,* gram-negative bacilli, and anaerobes. Mimics of pneumonia in the immunocompromised host include pulmonary emboli and infarction, congestive heart failure, metastatic or primary carcinoma, lymphangitic spread of carcinoma, alveolar hemorrhage, leukoagglutinin reactions, and radiation- and drug-induced pneumonitis.[88] An acute presentation of "pneumonia" suggests bacterial pneumonia, pulmonary emboli, congestive heart failure, or pulmonary hemorrhage. Subacute presentation suggests a fungal, nocardial, mycobacterial, or viral etiology (Table 183-3).[89,90]

Table 183-3 Pulmonary Infiltrates in the Immunocompromised Patient: Common Patterns of Disease and Differential Diagnosis

DIFFUSE BILATERAL INFILTRATES	FOCAL OR PATCHY INFILTRATES
Viruses	Bacterial pneumonias, including *Legionella*
Cytomegalovirus	Fungi
Respiratory syncytial virus	Invasive pulmonary aspergillosis
Influenza, parainfluenza	Zygomycosis (mucormycosis)
Adenovirus	*Fusarium*
Varicella	*Pseudallescheria*
Pneumocystis jiroveci	Tuberculosis
Fluid overload and pulmonary edema	Nontuberculous mycobacteria
Acute lung injury due to transfusion of blood products	Nocardiosis
Radiation damage	Pulmonary embolus
Chemotherapy-induced toxicity	
Acute respiratory distress syndrome due to viridans streptococcal bacteremia	
Bronchiolitis obliterans	
Pulmonary hemorrhage	
Progression of disease (lymphangitic spread of carcinoma, leukemic infiltrates)	

Diabetes

Diabetic patients have increased susceptibility to infection because of defects in immune function, excess substrate for fungal and bacterial growth, vascular insufficiency related to microangiopathy and atherosclerosis, and sensory neuropathy that leads to wound neglect.[91-93]

Neutrophil and monocyte-macrophage functions are impaired in diabetic patients, including adherence to bacteria, chemotaxis, phagocytosis, and intracellular killing. These defects are exacerbated by hyperglycemia and improved by tight glucose control. Although decreased lymphocyte proliferative responses to phytohemagglutinin and certain pathogens are described, cellular immunity appears normal or only minimally affected by diabetes. Humoral immunity is normal in diabetics.[94,95]

Infections seen with increased frequency in diabetic patients include rhinocerebral zygomycosis (formerly mucormycosis) caused by *Rhizopus* and *Mucor* species; malignant (or necrotizing) otitis externa caused by *P. aeruginosa*; pneumonia caused by *S. aureus* and gram-negative bacilli; tuberculosis, emphysematous cholecystitis, and urinary tract infections including emphysematous cystitis and pyelonephritis; polymicrobial necrotizing fasciitis involving the perineum (Fournier's gangrene) and lower extremities; and psoas abscess, spinal epidural abscess, and foot infections with osteomyelitis. Diabetics are not more likely to have pneumococcal pneumonia but are more likely to become bacteremic and to have a higher mortality rate.

www.ketabpezeshki.com 66485457-66963820

Alcoholism and Cirrhosis

Alcohol consumption predisposes to infection through direct suppression of the immune system, alterations in blood flow, depression of mental status, and delay in seeking medical care.[96]

With alcoholic cirrhosis, there is deficient hepatic clearance and killing of bacteria by reticuloendothelial cells as well as splenic hypofunction.[97] Complement deficiency occurs because the liver is the primary site of C3 synthesis. Neutrophils show impaired recruitment to infective sites and defective chemotaxis and phagocytosis.[98,99] Cellular immune deficiency occurs and is exacerbated by malnutrition. Bactericidal activity of IgM antibody against gram-negative pathogens such as *E. coli* and *H. influenzae* is decreased.

Acute ethanol intoxication is associated with granulocytopenia and diminished leukocyte mobilization that is reversible with abstinence. Ethanol intoxication interferes with most respiratory tract defense mechanisms, resulting in alterations of normal flora, impaired mechanical and cellular clearance because of a suppressed cough reflex, decreased ciliary motility, and resultant aspiration. These effects are often compounded by malnutrition, cigarette smoking, and chronic lung disease. Alcoholics exhibit an increased incidence of oropharyngeal colonization by gram-negative bacteria (35-59% of ambulatory alcoholic patients) compared with control subjects (14-18%). Alcoholics are also more likely to aspirate because of loss of reflex glottic closure associated with acute intoxication, withdrawal seizures, and encephalopathy.

Common infections include spontaneous bacteremia and sepsis caused by *E. coli, K. pneumoniae, Salmonella,* streptococci, *Vibrio vulnificus,* and *Aeromonas*; spontaneous bacterial peritonitis, usually caused by *E. coli, K. pneumoniae, S. pneumoniae,* or enterococci; pneumonia related to pneumococci, gram-negative bacilli (*E. coli, K. pneumoniae,* and *H. influenzae*), and anaerobes; tuberculosis; meningitis caused by *S. pneumoniae* and *L. monocytogenes*; and skin and soft tissue infections with *S. aureus,* streptococci, and gram-negative bacilli. Nasopharyngeal and cutaneous diphtheria also occurs.[100]

Renal Failure

Infections cause up to 20% of all deaths among patients with chronic renal failure and are the second most common cause of mortality after coronary artery disease.[101,102] Disruption of cutaneous barriers at vascular access sites and peritoneal dialysis catheter sites and numerous immune system defects are responsible for the increased incidence of infection. Uremic pruritus with excoriation, epidermal and sweat gland atrophy, dryness, and vesicular eruptions also compromise the cutaneous barrier. Reduced renal clearance of unknown toxins, nutritional deficiencies, and administration of immunosuppressive medications lead to aberrant immune regulation early in the course of renal failure.

Chronic kidney failure leads to a state of generalized immune hyporesponsiveness. Neutrophils show reduced mobility, chemotaxis, adherence, phagocytosis, and intracellular bactericidal activity, and leukopenia is commonly present. CMI is severely impaired, with decreased activation and proliferation of T lymphocytes and reduced NK cell activity, which cannot be reversed by hemodialysis. Furthermore, humoral immunity is adversely affected, resulting in deficient production of certain IgG subclass antibodies. Poor response to vaccines is common but can be improved by reinforced vaccination schedules, increased vaccine dosage, and adjunct immunomodulators.[103]

Additional predisposing factors to infection in uremic patients include low serum albumin, iron overload, increased intracellular calcium, circulating low-molecular-weight uremic toxins, metabolic acidosis, circulating inhibitors to chemotactic factors, decreased production of endogenous pyrogens, and invasive vascular procedures for dialysis access. The annual mortality rate from sepsis in dialysis patients is increased 100 to 300 times.[104]

Skin and soft tissue infections, especially those caused by *S. aureus,* are particularly severe in diabetics and in those with peripheral vascular disease or peripheral neuropathy. Vascular access site infections are usually caused by *S. aureus* but occasionally by gram-negative bacilli and enterococci. Patients using central venous catheters for dialysis have much higher rates of sepsis compared with fistulas or grafts. Bacteremia may lead to hematogenous osteomyelitis, usually involving the ribs or thoracic vertebrae, as well as endocarditis, meningitis, epidural abscess, and septic arthritis. Although the incidence of pneumonia is not increased overall in renal failure, it is often more severe, and there is an increased incidence of *Legionella* pneumonia. Tuberculosis and fungal infections caused by *Candida* species, *Cryptococcus, Histoplasma,* and *Coccidioides* occur with increased frequency. In addition, *C. difficile* colitis occurs more frequently and is more severe in patients with chronic renal failure. Infections of the urinary tract are more prevalent, with urinary bladder catheterization the most frequent predisposing factor. There is a poor correlation between the presence of pyuria and urinary tract infection in these patients. *Candida* infection of the urinary tract may develop in patients with chronic renal failure treated with broad-spectrum antibiotics.

Up to two thirds of patients receiving chronic ambulatory peritoneal dialysis have peritonitis in their first year, and one third may be forced to discontinue dialysis because of recurrent infections. *S. aureus* and *S. epidermidis* predominate, followed by streptococci, gram-negative bacilli, and *Candida* species. Fortunately, peritoneal dialysis patients have much lower rates of sepsis than those on hemodialysis do.

Splenectomy, Hyposplenia, and Functional Asplenia

The spleen is the most important organ in the reticuloendothelial system and the primary site for IgM synthesis, the first early immune response of the body. Opsonin production in the spleen facilitates phagocytosis of bacteria by intracellular macrophages. Patients without a spleen also have decreased production of neutrophils, NK cells, and immunomodulating cytokines.[105,106]

The spleen is the principal site of clearance of *S. pneumoniae* from the blood. Splenectomy or functional asplenia predisposes to overwhelming pneumococcal infection and fulminant infection with other encapsulated organisms (*H. influenzae, N. meningitidis,* and *Capnocytophaga canimorsus* after dog bites) and gram-negative bacilli (*E. coli* and *P. aeruginosa*). Asplenic people who become infected with *Babesia microti,* a malaria-like protozoan transmitted by tick bite in the United States, develop severe and often fatal hemolysis. Human granulocytic anaplasmosis (formerly ehrlichiosis), another tick-borne infection, is severe and sometimes fatal in asplenic patients. In addition, the gram-negative coccobacillus *Bordetella holmesii* produces a non–life-threatening acute febrile illness with bacteremia in patients with asplenia. Pneumococcal sepsis represents 50 to 90% of cases. Most healthy adults who die after fulminating pneumococcal sepsis have had a splenectomy or have a congenitally small or abnormal spleen.[107-110]

Overwhelming postsplenectomy sepsis is rare, and the true incidence is unknown because of a lack of prospective studies.[111] The risk is greater in children than in adults, and children younger than 2 years are at greatest risk. The risk is highest in the first few years after splenectomy but persists throughout life into old age. People undergoing splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection than are those undergoing splenectomy for

www.ketabpezeshki.com 66485457-66963820

trauma. This is probably because of the occurrence of splenic implants (splenosis) or accessory spleens in traumatized patients. Patients with functional asplenia from sickle cell anemia or thalassemia major are at high risk for overwhelming bacterial infections as well.

Functional hyposplenism occurs in a variety of conditions besides sickle cell disease, including sickle cell–hemoglobin C disease, ulcerative colitis, celiac disease, sarcoidosis, amyloidosis, rheumatoid arthritis, and SLE. The presence of anatomic or functional hyposplenism may be recognized by the finding of Howell-Jolly bodies in red blood cells on a peripheral blood smear.

When overwhelming postsplenectomy infection occurs, often no obvious source of infection is found. Prodromal symptoms, such as fever, rigors, malaise, myalgias, headache, vomiting, and diarrhea, may be present for 1 or 2 days.[112] Patients seen at this time may be misdiagnosed as having a viral illness, gastroenteritis, or food poisoning. Abrupt deterioration then occurs during hours, with rapid progression to septic shock with disseminated intravascular coagulation, purpura, and multiorgan dysfunction. The mortality rate is high (50-70%), with younger children having the highest mortality rate. In addition, meningitis without overwhelming infection or shock is a common presentation of pneumococcal infection in asplenic patients.[113] When fever develops in a person at risk for this disorder, treatment with an antimicrobial agent effective against *S. pneumoniae* should be initiated without delay. After blood culture is performed, the patient should receive ceftriaxone or cefotaxime, with addition of vancomycin in areas where penicillin resistance is prevalent. Clindamycin, levofloxacin, and moxifloxacin are alternatives for patients with serious penicillin allergy.

Use of pneumococcal vaccine in patients at risk is especially important now that antimicrobial-resistant *S. pneumoniae* is prevalent.[114] Asplenic people should be immunized against pneumococcus, *H. influenzae* type b, *N. meningitidis,* and influenza virus. People with functional hyposplenism related to serious underlying diseases often respond poorly to pneumococcal vaccine. Children should receive prophylaxis with oral penicillin or amoxicillin up to the age of 5 years and for at least 1 or 2 years after splenectomy, provided they have not had an invasive pneumococcal infection and have received pneumococcal immunizations. Long-term antimicrobial prophylaxis is generally not recommended in adults. These patients should have standby oral antibiotics at home (amoxicillin-clavulanate, levofloxacin, or moxifloxacin) with instructions to self-administer at the first sign of infection, and they should be provided with information and a medical alert bracelet. Fatal pneumococcal infection has occurred in patients immunized with pneumococcal vaccine who were also taking penicillin. An ED-based pneumococcal vaccine program, if it is implemented, could reduce mortality in high-risk patients while remaining cost-effective.[115,116]

IMMUNOSUPPRESSIVE THERAPY

Corticosteroids

High doses of corticosteroids alter the distribution and function of neutrophils, monocytes, and lymphocytes.[117] Corticosteroids suppress inflammation and enhance susceptibility to infection by impairing the mobilization and function of neutrophils and mononuclear cells at sites of primary lodgment of microorganisms in tissues. Corticosteroids inhibit neutrophil adherence to endothelium, decrease chemotaxis of neutrophils and monocytes, and inhibit phagocytosis and intracellular killing of microorganisms. Corticosteroids also severely impair CMI, probably a result of inhibition of the migration of lymphocytes to the site of antigen challenge, inhibition of lymphokine production, and consequent inhibition of lymphocyte proliferation. They also inhibit both classical and alternative pathways of complement activation. The hyperglycemia that occurs with corticosteroid use also contributes significantly to infection risk. Moreover, patients receiving high-dose corticosteroids have infection risks related to anatomic abnormalities of the underlying disease, treatment with other immunosuppressive agents, cancer chemotherapeutic agents, radiation therapy, and implantation of foreign bodies.[118-120]

Acute administration of corticosteroids produces marked alterations in circulating leukocyte numbers. Basophils, eosinophils, and monocytes decrease, whereas neutrophils are increased. These changes occur within 4 to 6 hours and abate by 24 to 48 hours after a single steroid dose. There is a redistribution of lymphocytes, predominantly T cells, out of the circulation, resulting in lymphocytopenia. Acute or chronic corticosteroid therapy has little effect on serum immunoglobulin levels.

The most common infections occurring in patients receiving high-dose corticosteroids are those caused by pyogenic bacteria (*S. aureus,* streptococci, and gram-negative bacilli). Despite the profound depression of CMI that occurs in patients taking corticosteroids, these patients generally have few infections commonly recognized as associated with defective CMI. The most common are tuberculosis and severe or disseminated infections caused by varicella-zoster and herpes simplex viruses. Patients receiving moderate doses of corticosteroids for asthma and other disorders are at increased risk for lethal primary varicella infection.[121] Other infections seen with corticosteroid use include those caused by *Listeria, Salmonella, Legionella, Nocardia, Candida, Aspergillus, Cryptococcus, Histoplasma, Coccidioides, Pneumocystis, Toxoplasma, Cryptosporidium,* and *Strongyloides*. Patients with neurologic diseases have much higher rates of infectious complications than do patients with intestinal, hepatic, or renal disease. The infectious complications related to corticosteroid use increase with doses of prednisone equivalents of more than 20 mg/day in adults, with total doses of more than 700 mg, and with treatment longer than 30 days. The risk of adrenal suppression can be decreased by use of prednisone doses less than 7.5 mg/day, administration of doses early in the day, avoidance of split doses, and use of alternate-day dosing.

Corticosteroids decrease leukocyte accumulation at inflammatory sites, and the whole cascade of responses leading to local manifestations of infection is slowed. These effects result in late presentation of serious infections. The ability of parietal cavities to localize sepsis is reduced. In addition, prolonged administration of corticosteroids results in delayed wound healing. For example, skin sutures should be left in place 50 to 100% longer than in normal patients. Short-term treatment has little effect on wound healing.[122]

The diagnosis of peritonitis resulting from perforation of colonic diverticula, appendicitis, peptic ulcer, or another primary intra-abdominal condition is particularly difficult.[123] These patients have abdominal discomfort, but they may have few abdominal findings and need rapid and aggressive investigation for life-threatening abdominal disease. CT scan of the abdomen and pelvis and surgical consultation may be needed emergently in these patients. Broad-spectrum antimicrobials to cover for gram-negative enteric bacilli and anaerobes should be administered without delay.

Other complications unrelated to the effects on the immune system include iatrogenic Cushing's syndrome, peptic ulcer disease, benign intracranial hypertension (pseudotumor cerebri), glaucoma, posterior subcapsular cataract, pancreatitis, avascular necrosis of bone (especially the femoral and humoral heads), psychosis, poor wound healing, hyperglycemia, diabetic ketoacidosis,

www.ketabpezeshki.com 66485457-66963820

hyperosmolar nonketotic diabetic coma, myopathy, and osteoporosis, resulting in vertebral compression fractures and other spontaneous fractures. In addition, adrenocortical insufficiency may occur on withdrawal of therapy.

Other Immunosuppressive Medications

Commonly used immunosuppressives include cyclosporine, tacrolimus, sirolimus, mycophenolate, azathioprine, methotrexate, and cyclophosphamide. They treat a wide variety of conditions, including rheumatoid arthritis, psoriasis, nephrotic syndrome, and inflammatory bowel disease, and they are used in the prevention and treatment of organ transplant rejection.[124] These drugs depress immune function, especially CMI. In addition, they have a narrow therapeutic window, wide-ranging toxic side effects, and many significant drug-drug and drug-food interactions. Patients may present for evaluation of symptoms caused by an adverse drug reaction or an infection. Before altering current medications, the physician needs to check carefully for drug interactions. For a more detailed discussion of the toxic effects of these agents, refer to Chapter 184.

Immunomodulating agents are available for treatment of a variety of immune-mediated inflammatory diseases, including rheumatoid arthritis, psoriasis and psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease. Some of these drugs include inhibitors of tumor necrosis factor alpha (infliximab, adalimumab, certolizumab, golimumab, etanercept), inhibitors of interleukins (tocilizumab, anakinra), inhibitor of pyrimidine synthesis (leflunomide), and inhibitor of T-cell activation (abatacept). These agents, particularly the tumor necrosis factor inhibitors, are associated with increased susceptibility to infection, particularly disseminated infection with various intracellular pathogens. Reactivation of latent infection with *Mycobacterium tuberculosis,* nontuberculous mycobacterial infection, histoplasmosis, and coccidioidomycosis is frequently disseminated and extrapulmonary at presentation. Additional infections seen at increased frequency include cryptococcosis, listeriosis, legionellosis, salmonellosis, aspergillosis, candidiasis, and pneumocytosis. The clinician should be alert to unusual manifestations of infection in patients taking these agents as misdiagnosis and delayed diagnosis increase mortality.[125-127] These drugs may also cause impaired wound healing, so skin sutures should be left in place for a longer time than is usual.[128]

KEY CONCEPTS

- Fever in the neutropenic patient is defined as a single temperature of 38.3° C (101° F) or higher or a temperature of 38.0° C (100.4° F) or higher during 1 or 2 hours. In neutropenic patients, the temperature should be measured orally or tympanically, not rectally.
- Fever in cancer patients with chemotherapy-induced neutropenia indicates infection until it is proved otherwise, most often caused by gram-positive (especially coagulase-negative staphylococci, *S. aureus,* viridans streptococci) and gram-negative (especially *E. coli, K. pneumoniae, P. aeruginosa*) bacteria but also occasionally by fungi (especially *Candida, Aspergillus*).
- Rapid diagnosis and early initiation of therapy are essential in preventing serious morbidity and mortality in immunocompromised patients, who often have subtle or unusual presentations and are difficult to diagnose. Early use of broad-spectrum antibiotics is indicated after appropriate cultures of all potential sites of infection, including intravascular catheters.
- Invasive aspergillosis originating in the paranasal sinuses may extend to the surrounding bone and brain. Often, an initial red-purple lesion on the nasal turbinate or palate turns pale and then black as vascular invasion produces infarction of the mucosa and bone. The black eschar on the nose or palate is easily misdiagnosed as dried blood.
- Patients with functional or surgical asplenia are at high risk for overwhelming sepsis from encapsulated bacteria, especially pneumococci, which may easily be misdiagnosed early in the course as a viral illness or food poisoning.
- Some infections are seen only below a certain CD4 cell count. *Pneumocystis* pneumonia is seen almost exclusively in patients with counts below 200 cells/mL (2×10^5 cells/L), whereas almost all patients with toxoplasmosis or cryptococcal meningitis have counts below 100 cells/mL (1×10^5 cells/L).
- If the chest radiograph is normal or inconclusive but there is still suspicion for pneumonia, high-resolution CT or thin-section multislice CT scanning of the chest without contrast enhancement should be obtained because pneumonia is often detected by chest CT in febrile neutropenic patients with normal findings on the chest radiograph.
- High doses of corticosteroids cause profound dysfunction of neutrophils and mononuclear cells and impair cell-mediated immunity, resulting in a marked increase in infections caused by pyogenic bacteria, varicella-zoster and herpes simplex viruses, tuberculosis, and a wide variety of other bacteria, fungi, and parasites.

Section Five
THE PATIENT WITH AN ORGAN TRANSPLANT

Chapter 184
The Solid Organ Transplant Patient

Matthew T. Keadey

PERSPECTIVE

The successful rehabilitation of patients with end-stage renal, pulmonary, hepatic, and cardiac failure through organ transplantation is one of the great achievements of modern biomedical science. Because 1-year survival rates for all solid organ transplants exceed 80% and many patients survive much longer, increasing numbers of transplant patients with complications are being seen in the emergency department (ED). Although organ transplant patients tend to seek care at their transplant center, many live a great distance from their facility and may require care at their local ED.

PRINCIPLES OF DISEASE

Transplanted organs are devoid of their native innervations and thus pain is an unreliable sign of underlying disease. Transplanted organs also have surgical anastomoses to a variety of structures, including vessels, bronchi, ureters, intestines, and even the bladder. Furthermore, the normal inflammatory and immunologic responses to infection and malignant disease are impaired. Subtle symptoms and signs may be the harbingers of serious complications, and each complaint merits careful investigation. Even in the most advanced stages of severe disease, patients may have few specific complaints and physical findings. The baseline physiologic capacity of the allograft will aid in interpretation of chief complaints in the context of possible organ failure. Small changes in allograft function may be a harbinger of an episode of rejection.

Transplant organ complications can generally be classified into one of four categories: anatomy, infection, rejection, and drug toxicity. Each category should be considered in the differential diagnosis for any transplant patient presenting to the ED. Often, the exact etiology is not determined until the patient is admitted to the hospital. In addition, time since transplantation must be considered in the evaluation. Time can help the clinician focus his or her investigative efforts and tailor treatment regimens.

Anatomy

Anatomic complications of solid organ transplants can be categorized into three groups: vascular, nonvascular anastomosis, and complications related to surgery. These are often manifested early in the post-transplantation course, but delayed presentations can occur.

Vascular complications can include both arterial and venous structures. Acute thrombosis of arteries may lead to fulminant organ failure. This is especially true in liver transplant recipients, in whom the hepatic artery is the sole source of blood flow for the biliary system. An ultrasound examination with color flow Doppler study is often performed immediately after liver transplantation to ensure arterial patency and flow. Arterial stenosis may also develop later in the course, with its effects typically determined by the degree of blood flow restriction. Pseudoaneurysms may develop and quickly lead to hemorrhagic shock if they rupture.

Nonvascular organ anastomoses may include bile ducts, bronchi, and ureters. Complications related to these structures include leaks and obstructions that often lead to acute graft dysfunction. Early identification is vital to salvage of the graft. Leaks are often manifested with pain and may lead to abscess formation. Conservative therapy may include antibiotics and percutaneous drainage. Refractory or severe cases may require surgical intervention. Obstructions may be due to scar tissue, migration of stents, or stone development. If the obstruction is not treated, graft dysfunction may lead to infections such as cholangitis and pyelonephritis. Bronchial leaks may cause a pneumothorax or pneumomediastinum. Prolonged leaks may lead to abscess formation in the thorax, requiring antibiotics and surgical drainage.

Complications related to the surgery are directly associated with the procedure but not specific to the transplanted organ. These may include problems related to technique that lead to hematoma or lymphocyte formation. Fever in the acute postoperative period must be evaluated for complications specific to the transplanted organ as well as for other common causes of postoperative fever.

Infection

Lifelong immunosuppression is generally necessary for all recipients of solid organ transplants, and infection is the primary cause of mortality after transplantation. Two thirds of transplant patients have at least one significant infection, most commonly nosocomial during the surgical recovery period or, subsequently, community acquired (Box 184-1).[1,2]

Signs of infection in this population of patients are often blunted by an impaired inflammatory response. Minor complaints or the chief complaint of a fever in an afebrile patient may herald a severe infection. Aggressive management usually translates into increased patient survival and graft function.[1]

Primary sources of infection in transplant recipients include pretransplantation, community acquired, transmission from organ donor, and nosocomial. Transplant patients should be vaccinated, but live viral antigens should be avoided. Close family members should not be given live vaccines because of the risk of transmission. The timing of infection can be separated into three periods: first month after transplantation, between 1 and 6 months after transplantation, and more than 6 months after transplantation. These distinctions help predict the etiologic agents of the infection.

Box 184-1 Infectious Pathogens in Transplant Patients

Exposure before Transplantation
Tuberculosis
Histoplasmosis
Coccidioidomycosis
Blastomycosis
Strongyloides stercoralis
Hepatitis B and C
Human immunodeficiency virus
Cytomegalovirus
Epstein-Barr virus
Varicella-zoster virus
Herpes simplex virus

Community-Acquired Exposure after Transplantation
Influenza
Primary varicella
Salmonellosis
Tuberculosis and fungal infections (see above)
Legionellosis
Nocardiosis
Cryptococcosis
Cytomegalovirus
Epstein-Barr virus

Nosocomial Exposure
Aspergillosis
Legionellosis
Pseudomonas aeruginosa and other gram-negative bacilli

Modified from Gorbach S (ed): Infectious Diseases. Philadelphia, WB Saunders, 1992.

First Month after Transplantation

Infections occurring in the first month after transplantation are likely to be related to the transplant procedure, stents, catheters, and intubation. In addition, the typical causes of postoperative fever should always be considered. Hospital-acquired pathogens are prominent, and management is similar for any immunosuppressed patient recently discharged.[2]

1 to 6 Months after Transplantation

Infections occurring 1 to 6 months after transplantation are divided into two general types: immunomodulating viral infections and opportunistic infections. Immunomodulating viruses include cytomegalovirus (CMV), hepatitis B and C viruses, BK polyomavirus, human herpesvirus 6, and Epstein-Barr virus (EBV). Opportunistic pathogens include *Pneumocystis*, *Listeria*, and fungal species.

CMV is the most important and prevalent immunomodulating virus 1 to 6 months after transplantation.[1] CMV infection may produce disease in multiple systems, but pneumonitis is particularly common and may be manifested insidiously. CMV infection may be primary or due to reactivation from latent viral particles found in lymphocytes. Typically, signs of CMV infection occur at a median of 40 days after transplantation. Survival from CMV infection is improving because of aggressive use of bronchoscopy that leads to earlier diagnosis and treatment with ganciclovir and CMV-specific immune globulin. Prophylaxis with ganciclovir reduces CMV incidence and death due to infection, but routine use of ganciclovir is associated with a number of potential side effects.[3] Because the risk of CMV infection is greatest during antilymphocyte therapy, some transplant centers administer ganciclovir only selectively during the treatment period, although CMV infection is still often fatal.[4,5]

Active CMV infection can trigger or exacerbate organ rejection. CMV is linked to a particular form of glomerulopathy in renal allograft recipients as well as acute hepatic dysfunction and the disappearing bile duct syndrome of chronic hepatic allograft dysfunction.[6,7] Furthermore, both acute cardiac dysfunction and accelerated coronary artery atherosclerosis of chronic heart transplant rejection are linked to CMV.[8,9]

EBV infection causes clinical effects similar to those of CMV infection. EBV contributes to immunosuppression and can cause a mononucleosis-like syndrome associated with lymphadenopathy, weakness, and low-grade fevers. Because CMV and EBV often coexist, both seem to trigger graft rejection. EBV is also implicated in B-cell lymphoproliferative syndrome, which is histologically similar to polymorphic B-cell lymphoma.[10]

6 Months after Transplantation

Six months after organ transplantation, patients with functioning solid organ allografts receiving immunosuppression therapy can be categorized into three groups relative to infection susceptibility: healthy transplant, chronic viral infection, and chronic rejection.

Healthy Transplant. Healthy transplant patients have no chronic immunomodulating viral infections and a functioning allograft; they are maintained with low doses of immunosuppressant medications. They have a mildly increased susceptibility to normal community-acquired infections, such as influenza, urinary tract infection, and pneumococcal pneumonia.

Chronic Viral Infection. Progressive disease may develop as a result of the combination of viral immunomodulating infections and long-term immunosuppression. Progressive liver disease due to recurrent or acquired viral hepatitis as well as hepatocellular carcinoma may occur. B-cell lymphoproliferative disorder associated with EBV infection may also develop.[1,2]

Primary varicella infection may lead to rapid dissemination with pneumonia, pancreatitis, hepatitis, encephalitis, and disseminated intravascular coagulation. Patients who are varicella-zoster virus (VZV) seronegative need high doses of intravenous varicella-zoster immune globulin after any exposure, preferably before the development of the rash. Therapy can be lifesaving if it is administered early before dissemination occurs.[1,2]

Reactivation of latent VZV infection, manifested as cutaneous herpes zoster, affects at least 10% of solid organ transplant recipients. Fortunately, reactivation of VZV is usually confined to a single dermatome and does not disseminate. Intravenous acyclovir therapy accelerates healing but does not change the incidence of painful neuralgia. Facial zoster involving the cornea and disseminated infections in more than one dermatome are indications for admission.[1] In patients who have never contracted VZV, many patients are immunized before transplantation.

Herpes simplex virus (HSV) reactivation is common after solid organ transplantation and can be manifested as oral or anogenital lesions, more often ulcers than vesicles. Some transplant centers prescribe oral acyclovir for 3 to 6 months after transplantation, whereas others choose to treat HSV immediately at the first sign of recurrence.[11]

Chronic Rejection. Patients with chronic rejection require ongoing aggressive immunosuppressive treatment to protect the allograft. These patients are at the highest risk for life-threatening opportunistic infections with fungi (e.g., *Candida, Cryptococcus, Coccidioides, Blastomyces,* and *Histoplasma*), bacteria (e.g., *Listeria* and *Nocardia*), and parasites (e.g., *Pneumocystis, Toxoplasma,* and *Strongyloides*).

Fungal infections are distinct to geographic regions and typically are manifested with subacute respiratory complaints associated with fever and focal, disseminated, or miliary infiltrates on the chest radiograph.[1] Invasive candidiasis and aspergillosis can also develop in the chronically immunosuppressed group. Primary

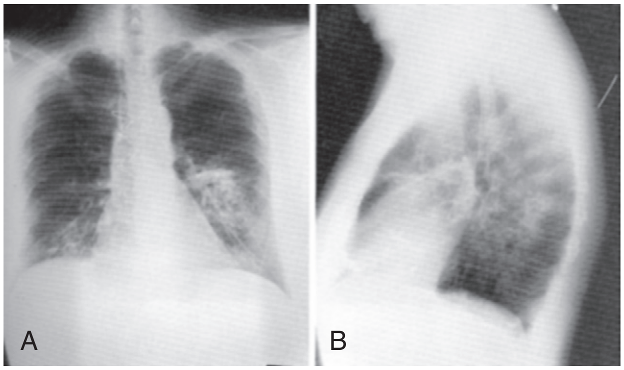

Figure 184-1. A and B, Bilateral perihilar and lower lobe alveolar infiltrates in a cardiac transplant recipient from *Pneumocystis jiroveci*. (From Tewari S, Maurer J: Pulmonary considerations of organ transplantation. In: Ginnes LG, Cosimi AB, Morris PJ [eds]: Transplantation. Malden, Mass, Blackwell Science, 1999, 617.)

infections in the lungs, gastrointestinal tract, or nasal sinuses lead to fungemia and contamination of intravenous lines and wounds. Treatment is with antifungal agents such as amphotericin B or agents such as micafungin (Mycamine).

Diverticulitis is the principal bacterial gastrointestinal infection observed in transplant patients with chronic rejection. Inflammation is suppressed with chronic steroid therapy, which leads to an increased incidence of perforation before diagnosis. Patients complain of an insidious onset of pain, change in bowel habits, and sometimes fever, but they typically lack peritoneal signs. Transplant patients are also susceptible to mucosal invasion with salmonellae (nontyphoidal) and *Listeria*. Infection with both organisms can be manifested as acute diarrheal syndromes that progress to bacteremia or meningitis.[1,2]

Pulmonary infection with *Nocardia asteroides* may occur in transplant patients. Primary infection is subacute, with cough, fever, pleurisy, purulent sputum, and subsequent metastatic infection of the brain and skin. Seizures or subcutaneous nodules may be the presenting complaint with a primary *Nocardia* infection.

Pneumocystis jiroveci (carinii) pneumonia is often found in combination with CMV infection because CMV inhibits alveolar macrophage function (Fig. 184-1). Fortunately, its incidence is reduced with prophylactic low-dose trimethoprim-sulfamethoxazole. Without prophylaxis, infection may develop 1 to 6 months after transplantation and is manifested subacutely with fever, nonproductive cough, progressive dyspnea, and an interstitial infiltrate on the chest radiograph. Differentiation from CMV pneumonia is impossible without bronchoscopic confirmation. Treatment of *Pneumocystis* pneumonia includes intravenous trimethoprim-sulfamethoxazole and steroids, depending on the degree of hypoxia.

Disseminated toxoplasmosis is a particular concern in heart transplant patients. Toxoplasmosis can lay dormant in the tissues, especially the heart, and be reactivated during immunosuppression, resulting in myocarditis, brain abscesses, or diffuse encephalitis. Typically, treatment of toxoplasmosis is a combination of intravenous sulfadiazine and pyrimethamine.

Strongyloides stercoralis, an intestinal nematode that normally causes minimal symptoms, can become an invasive pathogen during immunosuppression. A *hyperinfection syndrome* can develop, causing a necrotizing hemorrhagic enterocolitis and hemorrhagic pneumonia. Disseminated strongyloidiasis occurs when the larvae migrate from the gastrointestinal tract. Dissemination and hyperinfection can lead to gram-negative bacteremia and meningitis secondary to impairment of the blood-gut barrier.

Figure 184-2. A 22-year-old man with a kidney transplant who presented with fever and a cough was diagnosed with reactivated tuberculosis by sputum analysis.

Mycobacterial disease can be manifested as opportunistic reactivation or a primary infection. Even disseminated disease can be clinically silent, with invasion of the bowel, skin, and gastrointestinal tract. Pulmonary disease can be absent, miliary, or cavitary (Fig. 184-2). Treatment is difficult because typical agents can cause graft dysfunction.[1,2]

Rejection

The course of rejection may vary, but each individual typically has a lifelong course of a waxing and waning immune response to the allograft, mandating ongoing surveillance of allograft function. Differentiation of infection and rejection is often difficult in the ED. Determination is often made only after biopsy of the transplanted organ or positive culture results are identified.

Rejection typically occurs in three phases: hyperacute, acute, and chronic. *Hyperacute rejection* is rare with careful donor-recipient matching. It typically occurs in the immediate perioperative period. *Acute rejection* occurs within the first months after transplantation. The patient presents with constitutional symptoms and signs of transplant organ insufficiency. Expeditious laboratory assessment, including possible allograft biopsy, can confirm the diagnosis of rejection, and an appropriate adjustment can be made in the immunosuppressant regimen. If immunosuppression is stopped, acute rejection may occur at any time. *Chronic rejection* has a time course of years and results in the gradual failure of the transplanted organ over time.[12]

Drug Toxicity of Immunosuppression

Pharmacology of Immunosuppression

Immunosuppressive therapy requires correctly timed drug combinations to establish a delicate balance between immunosuppression, rejection, and susceptibility to infection. Multiple agents are standard. Regimens are typically transplant center specific, but most include a calcineurin inhibitor, an antimetabolite, and varying dosages of steroids. Recognition of the side effects,

www.ketabpezeshki.com 66485457-66963820

toxicities, and potential drug interactions of immunosuppressant medications is an important component in the care of any transplant patient.

A new term, *operational tolerance,* reflects long-term acceptance of transplanted organs without indefinite immunosuppression.[13] Allogeneic bone marrow transplantation from the solid organ donor may facilitate operational tolerance. Successful bone marrow transplantation may revolutionize the treatment of solid organ rejection and immunosuppressive therapy.

Accommodation, an acquired resistance of an organ to immune-mediated damage, has been recognized for more than 20 years. Initially, it was identified in blood group–incompatible kidney transplants that survived and functioned normally in recipients with high titers of anti–blood group antibodies directed against antigens in the grafts. Variable sublethal graft injury induces accommodation, and that may be a dynamic condition, eventuating into tolerance on the one hand and chronic graft injury on the other.[14]

Because of the toxicities of current immunosuppression medications, improvement in long-term transplantation outcomes may depend on new agents with novel mechanisms of action, devoid of the toxicities.[15] Inhibitors of pathways in B-cell and plasma cell activation, including belimumab and atacicept, combat the humoral immune response. Biologic agents for maintenance immunosuppression include monoclonal antibodies and fusion receptor proteins that target molecular pathways and enzymes.

Calcineurin Inhibitors

Cyclosporine. A variety of immunosuppression strategies are being tested, but the mainstay of transplant immunosuppression is cyclosporine.[16,17] Cyclosporine inhibits both cellular and humoral immunity by binding to cyclophilins, which block cytokine transcription and production, thereby inhibiting lymphocyte signal transduction. The result is a potent immunosuppression of helper-inducer T cells, without affecting the suppressor T-cell subset.[16,18] The helper-inducer T cells enhance antibody recognition and production by B cells.

Cyclosporine exhibits dose-related nephrotoxicity, which is additive to other nephrotoxic drugs typically used after transplantation, such as amphotericin B, aminoglycosides, and high-dose trimethoprim-sulfamethoxazole. Cyclosporine causes renal tubular injury and direct renal artery vasospasm in a dose-dependent manner, leading to systemic hypertension in many recipients.[16] Hypertension should be treated aggressively with standard regimens to preserve renal function and to prevent atherosclerosis. Cyclosporine may also aggravate hyperlipidemia, leading to atherosclerosis.[19] Therefore, monitoring of cyclosporine levels and renal function is routine.

Cyclosporine also causes hyperuricemia and gout in transplant patients. The nephrotoxic effects of cyclosporine complicate the management of gouty attacks in renal transplant patients.[20] Traditionally, nonsteroidals are the mainstay of gout therapy, but their use is limited in transplant patients receiving cyclosporine because of a potential synergistic nephrotoxic effect.

Cyclosporine levels are altered by many common post-transplantation medications (Table 184-1). Drugs that inhibit cytochrome P_{450} metabolism, such as erythromycin and ketoconazole, produce elevated cyclosporine levels and enhanced toxicity.[21] Treatment with rifampin can increase cyclosporine metabolism, which triggers episodes of organ rejection. Cyclosporine can also cause hepatotoxicity, hyperkalemia, hirsutism, tremor, and gingival hyperplasia.[16]

Table 184-1 Drug Interactions with Cyclosporine

AGENT	PHARMACOKINETIC ACTION	EFFECT
Carbamazepine Nafcillin Phenobarbital Phenytoin Rifampin	Induce cytochrome P_{450} enzymes	Decreased half-life and immunosuppressive effect
Colchicine Diltiazem Fluconazole Fluoroquinolones Ketoconazole Macrolide antibiotics Oral contraceptives Verapamil	Inhibit cytochrome P_{450} enzymes	Increased half-life and potential drug toxicity or immunosuppression
Aminoglycosides Amphotericin B Cimetidine Nonsteroidals Sulfur	Interact at a glomerular or tubular level	Increased nephrotoxicity

Tacrolimus

Tacrolimus is a macrolide compound that binds to lymphocyte proteins and inhibits cytokine synthesis. Because of an improved side effect profile and more effective immunosuppression, tacrolimus is used as either primary or rescue therapy for allograft rejection and is effective for rejection in all types of solid organ transplants.[22-24]

Like cyclosporine, tacrolimus causes nephrotoxicity as well as neurotoxicity. In combination with steroids, tacrolimus can lead to hyperglycemia and eventual secondary diabetes. Tacrolimus can also cause anorexia, diarrhea, dyspepsia, and nausea. Macrolide antibiotics should not be prescribed to patients receiving tacrolimus because of potential toxic levels.[22]

Antimetabolites

Azathioprine. Azathioprine is an antimetabolite derivative of 6-mercaptopurine. Long an important component of immunosuppressive therapy in solid organ transplants, azathioprine inhibits both deoxyribonucleic acid and ribonucleic acid synthesis, resulting in a suppression of lymphocyte proliferation. It is typically used in combination with other agents.[25] Since the introduction of the calcineurin inhibitor class, the use of azathioprine has been reduced because of cyclosporine's improved side effect profile.

Azathioprine is a bone marrow toxin, and patients exhibit dose-related neutropenia. The drug is given at the minimum effective dose to maintain a peripheral white blood cell count of 4000 to 6000 cells/mL. Azathioprine may also cause hepatic dysfunction and other gastrointestinal disturbances.[25]

Mycophenolate Mofetil. Mycophenolate mofetil (MMF) prevents and suppresses organ rejection after solid organ transplantation.[26,27] MMF is an antimetabolite with more potent and selective inhibition of lymphocyte proliferation. It reduces the incidence of acute rejection but with no significant change in the long-term survival of transplant recipients or their allografts.[18,25]

MMF has the advantage of a low side effect profile and should be used concomitantly with cyclosporine and corticosteroids when the patient can tolerate oral medication. The mostly mild effects resulting from its gastrointestinal and hematologic toxicity include abdominal pain, nausea, diarrhea, gastroenteritis, leukopenia, and thrombocytopenia. Because magnesium and aluminum antacids interfere with the absorption of MMF, care should be exercised in treatment of the gastrointestinal symptoms.[27]

Corticosteroids. Corticosteroids have been used for immunosuppression since the 1960s. Glucocorticoids have a wide range of effects on the immune system, specifically the T lymphocytes. Because of the significant long-term toxic effects associated with chronic glucocorticoid administration, every effort is made to

www.ketabpezeshki.com 66485457-66963820

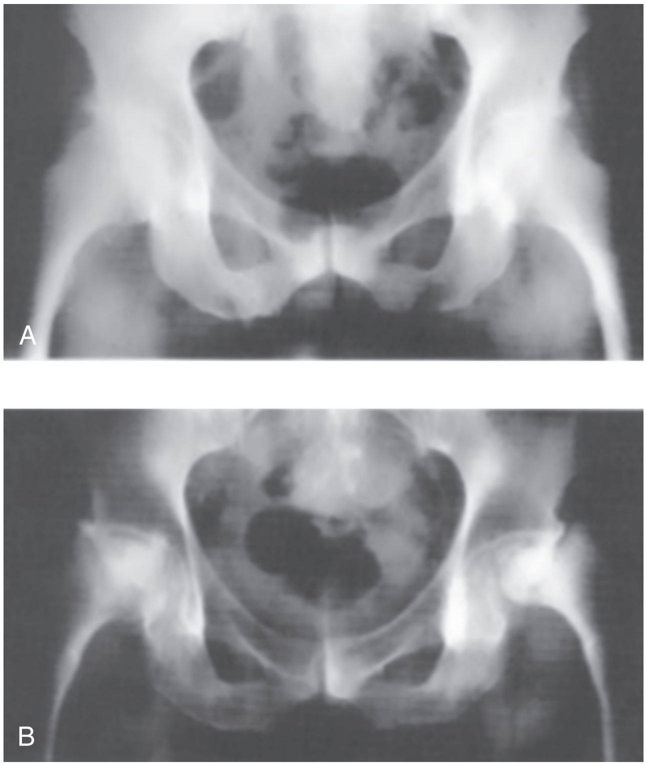

Figure 184-3. Radiographic appearance of a 24-year-old renal transplant patient with early (**A**) and late (**B**) findings consistent with avascular necrosis from chronic steroid use. (From Walker RG: Steroids and transplantation. In: Ginnes LG, Cosimi AB, Morris PJ [eds]: Transplantation. Malden, Mass, Blackwell Science, 1999, 121.)

minimize glucocorticoid use. *Combination therapy,* in which two or more immunosuppressants are administered simultaneously, decreases the reliance on long-term, high-dose glucocorticoid administration for allograft survival.[26]

Long-term corticosteroid therapy causes osteoporosis, cataracts, gastrointestinal bleeding, glucose intolerance, skeletal myopathy, bone disease, and adrenal suppression (Fig. 184-3).[28] Acute administration may lead to glucose and electrolyte abnormalities as well as altered mental status. Acute withdrawal or severe illness may lead to an addisonian crisis.

Antilymphocyte Monoclonal Antibody Preparations. OKT3 and antithymocyte globulin are used in short courses to reverse allograft rejection.[26,29] OKT3 is a mouse-derived monoclonal antibody to T cells. Chills, fever, hypotension, and headache often occur. Pulmonary edema may also develop in overhydrated, oliguric patients. OKT3 is effective in more than 90% of first rejections in most organs.[18]

OKT3 toxicity is common because of T-cell activation and lymphokine release caused by these agents. Patients receiving these agents are at increased risk of infection with opportunistic pathogens, particularly CMV. An increased risk of lymphoproliferative disease also exists.[26,29]

SPECIFIC DISORDERS

Clinical Features

The pertinent clinical features of organ transplant complications are extensive. Allograft rejection symptoms are usually vague and nonspecific. Complications of the organ often result in localized symptoms and dysfunction of the allograft. The clinical features of infectious complications depend on the nature of the pathogenic organism, location of the infection, and level of immunosuppression. The resuscitation of a traumatized transplant patient should focus on standard injury patterns.[30] Every complaint and finding in the organ transplant recipient should be examined in the most suspicious light to avoid missing catastrophic illness.

Diagnostic Strategies

Transplant patients should undergo liberalized laboratory and radiographic evaluation to rule out myriad infectious causes, to assess allograft function, and to survey for signs of drug toxicity. Laboratory assessments should include organ-specific measures of function and a careful search for evidence of infection. When infection is suspected, appropriate culture specimens and serologic studies should be obtained. Radiologic interventions focus on sources of infection and the relevant anatomy of the patient's allograft.

MANAGEMENT

Heart Transplant

General Approach

Human heart transplantation was first performed in 1967. Currently, more than 3000 procedures are done annually in the United States. The 5-year survival rates for adults and children are 72% and 80%, respectively.[31] Typically, the recipient heart is removed and replaced by the donor heart (orthotopic transplant), but the recipient heart is occasionally left in place with the donor heart anastomosed to the native vessels (heterotopic transplant) (Fig. 184-4).

Patients are usually discharged from the hospital within 2 or 3 weeks. In the Stanford experience, 37% of heart transplant patients made at least one ED visit in the ensuing 3 years (range, one to six visits). The most common complaints are fever (37%) and shortness of breath (13%). Sixty percent of these patients are admitted, compared with an overall ED admission rate of 15%. The most common ED diagnoses are sepsis (18%), rejection (11%), and pneumonia (8%).[19]

Treatment of the traumatized transplanted heart should not differ from that of native hearts. Baseline tachycardia is expected because of denervation of the vagus nerve. Despite the absence of a pericardium, scarring and adhesions may result in clinical tamponade with pericardial fluid or blood. Blind pericardiocentesis should not be attempted.[30]

Infection and rejection are the leading causes of mortality in the first year. Any heart transplant patient presenting to the ED with congestive heart failure (CHF), fever (temperature above 38.0°C), shortness of breath, hypoxia, hypotension, poorly controlled hypertension, syncope, or new dysrhythmia should be admitted. Chest pain is rarely related to cardiac ischemia because the denervated heart is incapable of producing angina.[32] Accelerated atherosclerosis of the graft vessels is the hallmark of chronic rejection. Ischemia is manifested as CHF, ventricular dysrhythmias, hypotension, syncope, or sudden death.[33,34] CMV infections also appear to be a risk factor for accelerated atherosclerosis.[9,21,35]

Drug Toxicity

Lifelong immunosuppression is required; most centers use a three-drug regimen of cyclosporine, prednisone, and azathioprine. Each drug has potential for toxicity, and the combination of cyclosporine and prednisone aggravates hyperlipidemia in many patients.[19,36] Rarely, cyclosporine toxicity can result in a

www.ketabpezeshki.com 66485457-66963820

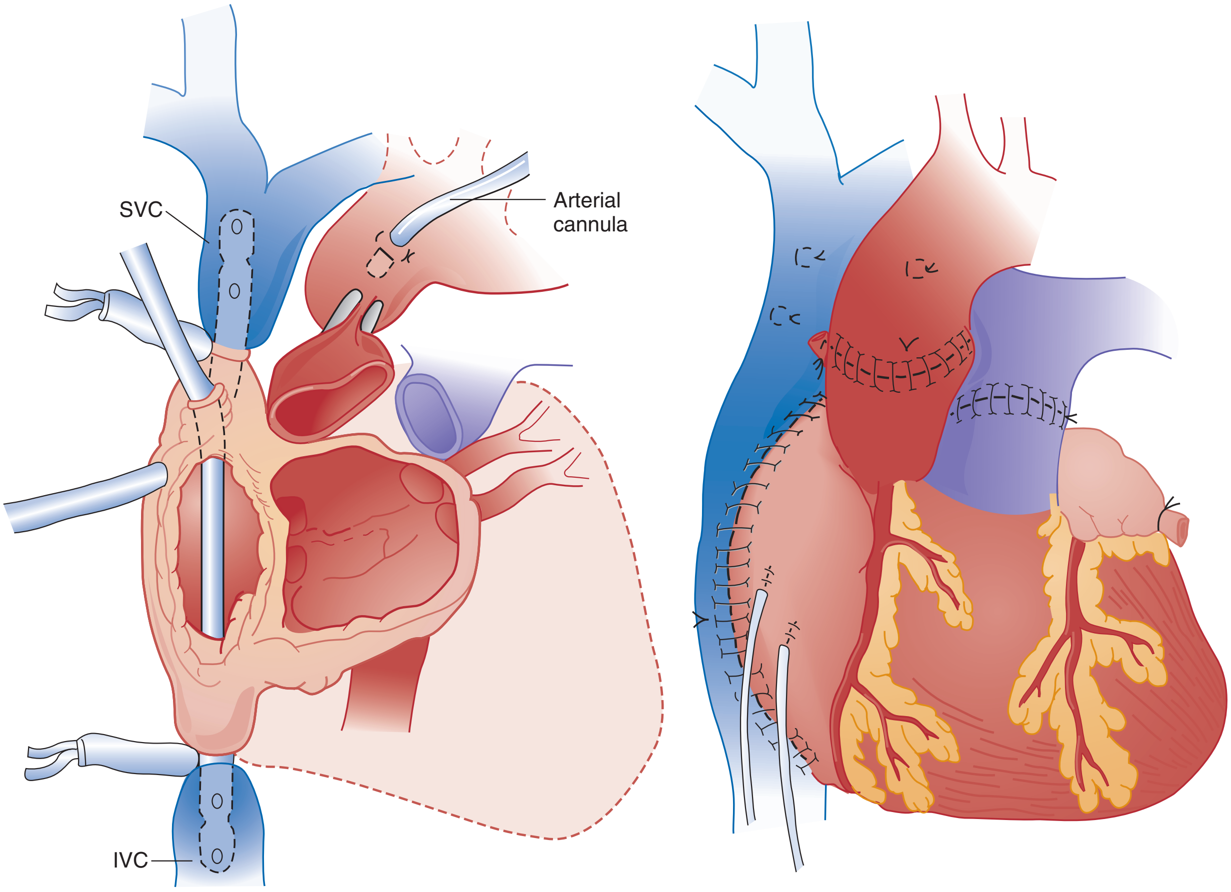

Figure 184-4. **A** and **B,** Typical anastomoses of an orthotopic heart transplant. *IVC,* inferior vena cava; *SVC,* superior vena cava. (From Hunt SA, Schroeder JS, Berry GJ: Cardiac transplantation, mechanical ventricular support, and endomyocardial biopsy. In: Furster VL, et al [eds]: Hurst's The Heart. New York, McGraw-Hill, 2001, 729-730.)

neurotoxic syndrome of seizures, confusion, cortical blindness, and quadriplegia, progressing to coma if it is left untreated.[37-39]

Rejection

Of patients who have acute rejection, 75 to 85% do so within the first 3 months. Manifestations may be subtle when cyclosporine is included in the immunosuppressive regimen. Previously, rejection was obvious, with decreased QRS voltage, a new S_3 heart sound, new-onset CHF, or dysrhythmias. These features are now present only during episodes of severe rejection, and the diagnosis often requires endomyocardial biopsy showing lymphocyte infiltration or myocyte necrosis.[1,19] Because most episodes of early or mild rejection are asymptomatic, frequent biopsies are performed to monitor the success of the immunosuppressive regimen throughout the transplant patient's lifetime.[40,41]

Acute rejection is treated with increased doses of corticosteroids (methylprednisolone, 500-1000 mg/day) and cyclosporine or with OKT3 or antithymocyte globulin. Immunosuppression is continued lifelong, with endomyocardial biopsies at least every 3 to 6 months.[41,42]

Without parasympathetic tone, the transplanted heart maintains a rate of 100 to 110 beats/minute. The electrocardiogram typically demonstrates two P waves. One wave is from the native sinus node in the posterior right atrium, which is often left in place. The second P wave is from the donor sinoatrial node, which should conduct to the ventricles as usual with a normal PR interval. In the rare heterotopic heart transplant, bizarre electrocardiographic recordings may be seen that do not conform to normal standards (Fig. 184-5).

The transplanted heart rate can increase with exercise or stress through the effects of endogenous catecholamines, up to 70% maximum for age. Exogenous pressor agents are effective in the transplanted heart. Upregulation of beta-adrenergic receptors appears to occur in the graft, with a slightly enhanced response to norepinephrine and isoproterenol.[37,42-44] Typical antihypertensive agents can be used as in the nontransplant patient. Atropine is ineffective because of vagal denervation.

Infection

The most vulnerable period for infection is the first 3 months, when immunosuppression is maximal. One quarter of deaths after transplantation result from infection. Although one third of patients will have a major infection develop in the first year after transplantation, life-threatening infection after 1 year is rare.[1,21]

In the first month, nosocomial infection predominates, with the usual gram-positive and gram-negative bacteria. After the first 3 months, patients experience an overall 20% per year rate of infection. The most common skin infection is herpes zoster, which is treated with high-dose acyclovir. Nausea, vomiting, or diarrhea should prompt a search for CMV by culture and serologic testing.[2,19,40]

All heart transplant patients with fever should be aggressively evaluated unless a minor source of infection, such as an upper

www.ketabpezeshki.com 66485457-66963820

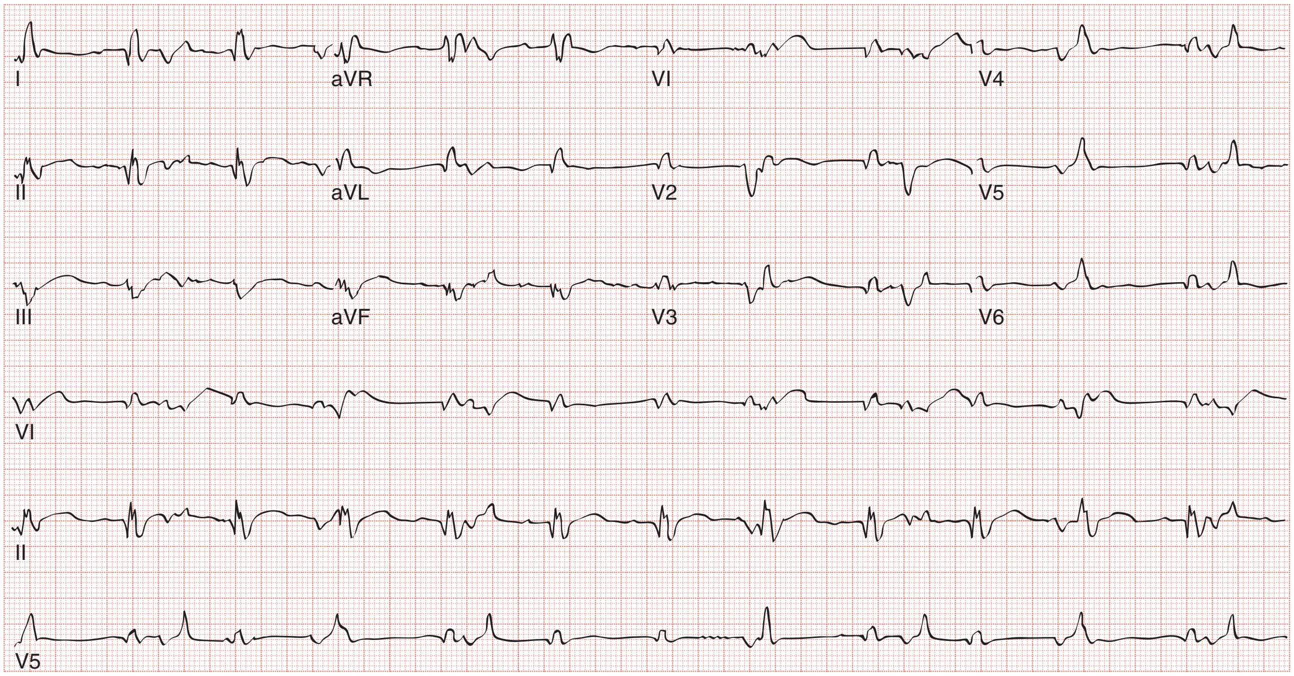

Figure 184-5. A 68-year-old man status post–heterotopic heart transplantation; native heart rate of 55 beats/minute and donor heart rate of 75 beats/minute.

respiratory infection, is obvious. The diagnostic workup in the ED can include blood and urine cultures, computed tomography (CT) scan, lumbar puncture, and bronchoscopy. In addition, complete blood count, glucose concentration, serum chemistries, blood urea nitrogen and creatinine concentrations, chest radiography, and electrocardiography are recommended. In one series of 131 ED visits by such patients, 23 patients were admitted with a diagnosis of "rule out sepsis," and an infecting organism was identified in 12 (52%).[19,37,41]

Any new headache with or without visual changes may be the first symptom of meningitis or brain abscess, and a CT scan of the head and a lumbar puncture should be obtained. Fever, lethargy, headache, altered mental status, and seizures are presenting signs of *Listeria* infection, cryptococcal meningitis, *Toxoplasma gondii* infection, or brain abscesses from *Nocardia* or *Aspergillus*. A more definitive diagnosis can often be made through biopsy or drainage. Aseptic meningitis may also occur in 10 to 14% of patients treated with OKT3 approximately 6 to 10 days after therapy but may be difficult to differentiate from other causes by cerebrospinal fluid analysis alone.[1,21]

Because of the attendant risk of endocarditis, antibiotic prophylaxis should be provided for invasive procedures likely to cause bacteremia. VZV immune globulin is recommended as soon as possible when seronegative patients are exposed to chickenpox or herpes zoster.[2,19]

Liver Transplant

Liver transplants have 1- and 3-year survival rates of 86% and 76%, respectively.[31] Complications are common, and loss of function of the graft organ is rapidly life-threatening.

Anatomic Considerations

The typical liver transplant is connected to its host through five anastomoses (Fig. 184-6). The vessels are connected first, allowing organ reperfusion. The biliary system is then reconstructed and often stented with a T tube to prevent stenosis. In the early post-transplantation period, T tubes may be replaced if restenosis develops. The most common vascular complication is hepatic artery thrombosis, which most commonly occurs in the early post-transplantation period. Severe graft dysfunction is invariable, and mortality approaches 75%.[45]

Rejection

Liver transplant rejection is the norm despite immunosuppressive therapy. Rejection often begins 1 or 2 weeks after surgery, with fever, right upper quadrant pain, and elevated bilirubin and transaminase levels. Leukocytosis may occur but is nonspecific. Related conditions that simulate graft rejection are mechanical biliary obstruction, primary nonfunctioning graft, ischemia from thrombosis of vascular anastomoses, viral infections, drug toxicity, and recurrent primary disease.[46-49]

As soon as transplant rejection is suspected, hospitalization and treatment with high-dose methylprednisolone should begin. If steroids fail, OKT3 monoclonal antibodies are used in addition to polyclonal antilymphocyte globulin.[46]

Infection

After the first postoperative month, viral (CMV and HSV), fungal (*Aspergillus, Candida,* and *Cryptococcus*), protozoan (*Pneumocystis* and *Toxoplasma*), and unusual bacterial (*Nocardia, Legionella,* and *Listeria*) infections occur. In addition, ascending cholangitis due to colonization of biliary stents with staphylococcal species, enterococci, and gram-negative organisms is common. Subsequent injury to the graft during biopsy or cholangiography can also cause cholangitis or liver abscess.

Kidney (Renal) Transplant

With survival rates of 96% at 1 year and 91% at 3 years, kidney transplants are the most successful of the solid organs.[31] Kidney transplantation provides better long-term survival than dialysis does. The best survival is in patients who receive transplants

www.ketabpezeshki.com 66485457-66963820

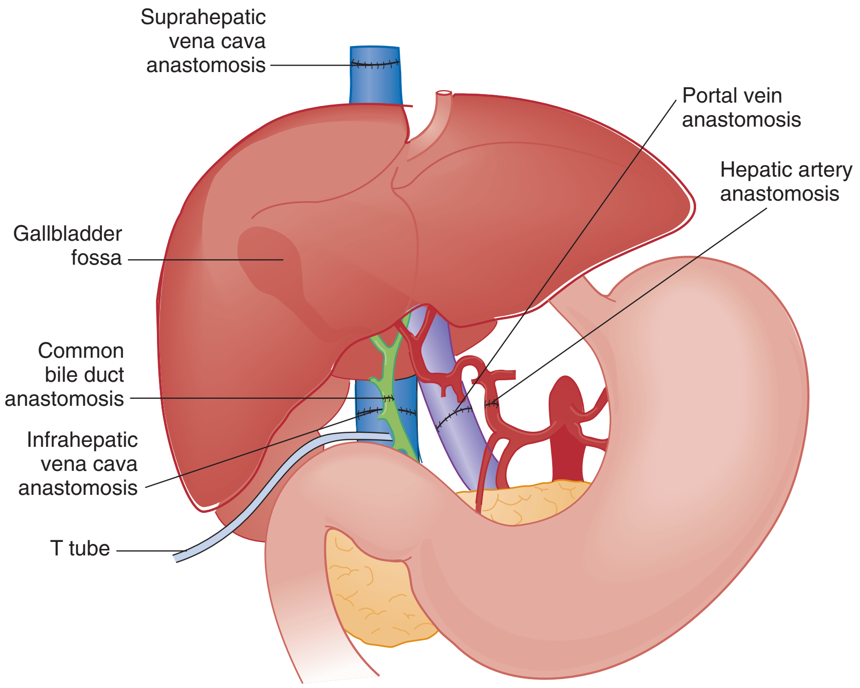

Figure 184-6. Typical anastomoses of an orthotopic liver transplant. (From Powelson JA, Cosimi AB: Liver transplantation. In: Ginnes LG, Cosimi AB, Morris PJ [eds]: Transplantation. Malden, Mass, Blackwell Science, 1999, 352.)

before they need dialysis, otherwise known as preemptive transplantation.[50] Eventually many kidney transplant patients may avoid the sequelae of end-stage kidney disease and many of the complications of dialysis. Parenthetically, traumatic injury of the transplanted kidney is rare, despite its location in the retroperitoneal area of the anterior pelvis, where it may be at risk from direct blows and seat belt injuries.[30]

Infection

The classic example of bacterial infection in transplanted organs is pyelonephritis in renal allografts, which often occurs in the first month after surgery during high-dose immunosuppression. During this period, an increased risk of sepsis exists. Gram-positive organisms associated with wound infections and gram-negative organisms are the predominant causes. Pyelonephritis occurs in 35% of patients during the first 4 months, but the incidence can be reduced by prophylactic antibiotics. All transplant patients who have pyelonephritis are admitted for aggressive antibacterial therapy.[51,52]

Hepatitis C virus (HCV) infection is the most common cause of hepatitis in renal transplant patients. It may be transferred to the recipient by blood transfusion or through the donor organ because pretransplantation antibody testing is a poor predictor of latent HCV infection. Liver disease develops in approximately 50% of seropositive patients, occurring approximately 4 months after transplantation. Most patients have chronic hepatitis with an increased susceptibility to sepsis and spontaneous bacterial peritonitis. Pretransplantation screening is the only avenue of prevention.[1,52]

Rejection

Early kidney transplant rejection is mediated through T lymphocytes against antigen donor tissues, including cytotoxic CD8 and CD4 cells. In addition, B lymphocytes, natural killer cells, and macrophages infiltrate the foreign tissues. The B lymphocytes manufacture specific antibodies, which results in microvascular lesions that impair perfusion.

Chronic transplant rejection occurs after several years of adequate function and is a result of nephrosclerosis. This process involves proliferation of the vascular intima of renal vessels with marked decrease in the lumen size. Systemic hypertension ensues as the graft fails from ischemia, with resultant tubular and glomerular atrophy.

With cadaveric kidney transplants, histocompatibility differences are almost universal and routinely require long-term immunosuppressive therapy. This is accomplished with a combination of azathioprine, prednisone, and cyclosporine. On diagnosis of acute rejection, high-dose intravenous methylprednisolone (500-1000 mg) is begun daily and continued for 3 days. After 6 to 12 months, many patients need only lower doses of prednisone (10-20 mg/day) to maintain immunosuppression.[51,52]

Clinically, renal graft rejection is manifested with fever, swelling and tenderness over the allograft, and decreased urine output. A subtle rise in serum creatinine concentration should prompt great concern. Renal ultrasound examination with color flow Doppler study should be performed to rule out obstruction, abscess, vascular thrombosis, and perirenal collections of blood, pus, or lymph.[52] Early consultation with the nephrologist is prudent.

Lung Transplant

Reasonably compelling data document the beneficial impact of lung transplantation on functional status, hemodynamics, and quality of life, but the data are less compelling to prove a survival benefit.[53] The lung may be transplanted alone or in combination with the heart, with 1-year survival rates of 76% and 56%, respectively.[31] Lung transplants are typically done unilaterally, except for cystic fibrosis. Unequal lung sounds are to be expected. There is no published experience with lung injury after transplantation. Comparison of chest radiographs with preinjury studies is critical in the evaluation of trauma. Chest tube place-

www.ketabpezeshki.com 66485457-66963820

ment on the transplanted side may be difficult because of adhesions and loculations.[30]

Rejection

Although lung transplantation is still rare, it is increasing in frequency; more than 800 are performed annually in the United States.[31] Most patients have early rejection, and 25 to 40% have chronic rejection. An episode of acute rejection can occur as early as a few days after transplantation or as late as several years. Clinically, the patient presents with cough, dyspnea, and fever. Rales and rhonchi are heard, with deterioration in oxygenation and pulmonary function. Early rejection is often accompanied by infiltrates on the chest radiograph. When rejection occurs more than a month after transplantation, 75% of radiographs are normal or unchanged. The diagnosis of rejection is made by transbronchial biopsy showing lymphocytic infiltration.[21,54-56]

Suspected episodes of acute rejection are treated with high-dose methylprednisolone (500-1000 mg/day). This is successful in reversing most episodes, but OKT3 can be used in refractory cases.[55]

Chronic lung transplant rejection is a leading cause of late morbidity and mortality. Antecedent acute rejection and CMV pneumonia are risk factors. On pathologic examination, vascular sclerosis and progressive limitation to airflow occur from obliterative bronchiolitis. Rejection can occur several years after transplantation, but the mean time to onset is 8 to 12 months. Clinically, this rejection mimics an upper respiratory infection or bronchitis. If dyspnea is a component of the presenting complaint, a search for transplant rejection should be initiated.[55,57]

Chronic rejection is treated with high-dose methylprednisolone (500-1000 mg/day). Antilymphocyte antibodies are used as well, but relapse of the rejection episode is common.

Infection

Transplanted lungs are highly susceptible to pneumonia because they can be colonized by bacteria during the ventilator stage of the brain-dead donor. After transplantation, diminished mucociliary clearance, decreased cough reflex due to denervation, and defective function of alveolar macrophages are present. The most common infections are caused by gram-negative bacteria such as *Pseudomonas* and by *Staphylococcus aureus*. Antibiotic therapy should be aggressively directed toward any pathogenic bacteria cultured from the tracheobronchial tree. Community-acquired pneumonia should be considered as well. *Pneumocystis* pneumonia is uncommon because of routine prophylaxis with trimethoprim-sulfamethoxazole.[1,55]

CMV pneumonia is the most common opportunistic pulmonary infection after lung transplantation. Patients are at highest risk between 3 weeks and 4 months. Clinically, CMV infection closely resembles transplant rejection. Tissue biopsy and viral culture are required to differentiate the two entities. Treatment with ganciclovir is effective and is often required long term (>12 months). Colonization by *Candida* is common, but invasive disease with *Aspergillus* and *Candida* provides the most significant fungal threat to the transplanted lung. When these species are invasive, they can cause bronchiolitis obliterans syndrome by inflammation and obstruction of the bronchioles.[58] Reactivation of tuberculosis is rare.[55,56]

Pancreas Transplant

The pancreas may be transplanted singly or in combination with a kidney. This is typically secondary to diabetes. Isolated pancreatic transplants have a high complication rate, with 1-year graft survival rates as low as 72%. Because the exocrine functions of the allograft pancreas are usually drained into the bladder, genitourinary complaints are also common. Duodenocystostomy fistulas may form in the early post-transplantation period. The clinical findings are abdominal pain, tenderness, hyperamylasemia, leukocytosis, and elevated serum creatinine. Other types of pancreatic transplant complications include urinary tract infections, hematuria, reflux pancreatitis, rejection, and pancreatic graft thrombosis.[59-61]

Anatomic considerations are important when these patients suffer major trauma because pancreas transplants are placed in the pelvis overlying the iliac vessels.[30] Exocrine secretions are drained into the bladder for excretion, and patients have a chronic non–anion gap acidosis through loss of bicarbonate into the bladder. This should not be confused with lactic acidosis. These trauma patients should not require exogenous insulin unless the graft is injured. Positive amylase on peritoneal lavage (CT is recommended if the patient is stable) can result from either native organ or graft trauma or from a ruptured bladder. CT scanning should be done with rectal administration of contrast material, in addition to intravenous and oral agents, to better define the native and transplanted pelvic organs.[30]

Islet cell transplantation is under investigation as a treatment of diabetes mellitus and has entered the mainstream of therapy. Although the procedural complication rate is significantly less compared with a whole pancreas transplant, islet transplantation requires several donors for adequate islet cell mass to achieve insulin independence. In addition, there is an increased attrition of islet graft function that occurs during the first few years compared with whole pancreas transplantation. As a result, these factors have made whole pancreas transplantation the most commonly performed type of beta cell replacement therapy.[62]

PSYCHOLOGICAL ASPECTS OF ORGAN TRANSPLANTATION

The psychological issues that surface while an individual is under consideration for an organ transplant or after transplantation affect many patients. Organ transplantation is no longer considered experimental, and it is a common therapeutic option for end-stage organ failure. Strong emotions naturally occur and should be acknowledged in donors, recipients, and transplanters.

Transplant programs widely use psychosocial selection criteria. In general, the cardiac programs have the most stringent criteria. The side effects of lifelong immune suppression or steroid withdrawal can include anxiety, depression, and insomnia. On the other hand, successful transplantation often improves psychological well-being. Transplant social workers can provide awareness of and access to the social network that should surround each transplant recipient. Long-term compliance with all aspects of treatment will minimize graft rejection.[63]

DISPOSITION

Patients with solid organ transplants presenting to the ED have a much higher than average rate of hospitalization.[31,49] The insidious nature of the diseases affecting this immunosuppressed population necessitates a thorough structured approach to evaluation. If organ rejection, infection, or drug toxicity is suspected, local transplantation specialists should be consulted. Physicians without significant transplant experience should contact the patient's transplant center to obtain consultation and to coordinate follow-up care. Patients who are discharged require careful instructions and close follow-up.

The continuing shortfall of organs for transplantation has increased the use of donation after cardiac death (DCD). Some patients with catastrophic injuries in the ED might have potential for controlled DCD. Identification of potential donors after

www.ketabpezeshki.com 66485457-66963820

cardiac death in the ED with appropriate use of critical care for selected patients may contribute to a reduction in the shortfall of organs for transplantation.[64] Although this area remains controversial, most states require that the local organ procurement network be contacted for any recently deceased patient.

KEY CONCEPTS

- The possibility of organ rejection, infection, or drug toxicity should be considered in all organ transplant patients who present to the ED despite subtle presentations.
- A patient's inability to take oral immunosuppressants for even a single day should be considered an emergency condition.
- When prescribing care in the ED, the physician should be careful to avoid drug interactions and toxicity.
- Infections that occur 1 to 6 months after transplantation are generally immunomodulating viral infections, such as with CMV, or opportunistic infections.
- Close family members of transplant patients should not receive live viral antigen vaccines because of the risk of transmission.
- Differentiation of infection and rejection is often difficult in the ED. Determination is often made only after biopsy of the transplanted organ or positive culture results are identified.

Section Six

THE ALCOHOLIC AND SUBSTANCE ABUSE PATIENT

Chapter 185

Alcohol-Related Disease

John T. Finnell

PERSPECTIVE

As eloquently stated by Paracelsus in the 16th century, "all substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy."

Epidemiology

The disastrous effects and widespread incidence of alcoholism are well known to the emergency physician. Almost all societies that consume alcohol show related health and social problems.[1] Motor vehicle collisions, drowning, suicides, homicides, divorce, violent crime, child abuse, unemployment, and disruption of the family are often either directly or indirectly associated with excessive alcohol consumption. The tragic effects of alcohol not only affect the individual drinker but also have far-reaching implications for the family, community, and workplace. In the United States, an estimated 7.6 million visits to the emergency department (ED) a year are related to alcohol, accounting for 7.9% of all ED visits.[2] Table 185-1 lists the causes of death related to alcohol abuse.

Alcohol is the most common recreational drug taken by Americans, and per capita consumption is increasing. An estimated 18 million alcoholics live in the United States; with more than 85,000 alcohol-related deaths each year, resulting in 2.3 million years of potential life lost,[3] alcohol is the third leading cause of preventable death in the United States.[4] Alcoholism permeates all levels of society and is a preventable cause of morbidity and mortality, with a cost to the nation estimated to be greater than $185 billion annually.[5]

The alcohol-use disorders consist of alcohol dependence, alcohol abuse, and dependence or harmful use. These disorders are common in all developed countries and are more prevalent in men than in women, with lower but still substantial rates in developing countries. However, most people with alcohol-use disorders are difficult to identify because they are likely to have jobs and families and to present with general complaints, such as malaise, insomnia, anxiety, sadness, or a range of medical problems.

Diagnosis

Alcohol dependence is associated with major physiologic consequences and life impairment. Dependence can be identified as repetitive problems, affecting three or more areas of life, and about 80% of people who are diagnosed with dependence at any point still have alcohol-related problems when they are assessed a year or more later.[6] Dependence criteria are reliable across different ages, sexes, and most cultural groups. Alcohol abuse is defined by the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition (DSM-IV), as one or more problems with functioning in a 12-month period in a person without dependence: failure in obligations; alcohol use in hazardous situations; recurrent legal problems; or continued use despite social or interpersonal problems.[7]

Alcohol Screening Questionnaires

Detection of risky drinking behaviors can be through clinical history or the administration of short alcohol screening tools in the ED setting, such as the Alcohol Use Disorders Identification Test (AUDIT), Fast Alcohol Screening Test (FAST), and CAGE questionnaires. The objectives of these screening tools vary; the AUDIT and FAST are focused on detection of recent hazardous or harmful alcohol consumption and associated problems, whereas the CAGE is designed to detect lifetime alcohol dependence.

The AUDIT-C Screening Questionnaire

1. How often do you have a drink containing alcohol?
   Never (0 points), monthly or less (1 point), two to four times a month (2 points), two or three times a week (3 points), four or more times a week (4 points)
2. How many drinks containing alcohol do you have on a typical day when you are drinking?
   1 or 2 (0 points), 3 or 4 (1 point), 5 or 6 (2 points), 7 to 9 (3 points), 10 or more (4 points)
3. How often do you have six or more drinks on one occasion?
   Never (0 points), less than monthly (1 point), monthly (2 points), weekly (3 points), daily or almost daily (4 points)

Scoring: The sum of scores for the three questions results in an AUDIT-C score of 0 to 12 points.

The AUDIT-C screening thresholds are ≥4 points for men (sensitivity 86%, specificity 89%) and ≥3 points for women (sensitivity 73%, specificity 91%).

A positive answer to the question Have you ever had a drinking problem? plus evidence of alcohol consumption in the previous 24 hours provides greater than 90% sensitivity and specificity as a screening tool for identification of alcoholism.

Blood tests can be useful if the history is in doubt and can also help patients recognize that alcohol has adversely affected their health. One such marker is γ-glutamyltransferase, an enzyme important in amino acid transport. Results of at least 35 units/L indicate the probability of heavy drinking. A second test is for carbohydrate-deficient transferrin, which measures a change in the structure of a proportion of transferrin that is likely to occur with heavy drinking during a long period; a result of 20 units/L or more indicates heavy drinking. Tests of liver function that measure aspartate transaminase (AST) and alanine transaminase (ALT) can identify heavy drinking and alcohol-use disorders with

www.ketabpezeshki.com 66485457-66963820

sensitivities of 25 to 45% and specificities as high as 90%. A ratio of AST to ALT higher than 2, especially if concentrations of these enzymes do not exceed 400 units/L, suggests alcoholic hepatitis. Although many newer biomarkers are not yet available, these newer markers (acetaldehyde adducts) rely on protein modifications by acetaldehyde and play an important role in the pathogenesis of tissue damage in alcoholics (Tables 185-2 and 185-3).

Pathophysiology

Causes and Origins

About 40 to 60% of the risk of alcohol-use disorders is explained by genes and the rest through gene-environment associations. The environment includes the availability of alcohol, attitudes toward drinking and drunkenness, peer pressures, levels of stress and related coping strategies, models of drinking, and laws and regulatory frameworks.

First, variations (polymorphisms) in genes for enzymes that metabolize alcohol are generally associated with a lower risk of alcohol-use disorders because they increase sensitivity to alcohol. At least one variant of aldehyde dehydrogenase (the *ALDH2*2* allele) produces an aversive response to alcohol. Second, gene forms associated with impulsivity, disinhibition, and sensation seeking contribute to vulnerability to both drug-use and alcohol-use disorders, perhaps through impaired judgment and difficulty in learning from mistakes that could reduce control of alcohol intake. Relevant polymorphisms include variations in receptors for γ-aminobutyric acid (e.g., *GABRA2*), acetylcholine (e.g., *CHRM2*), and dopamine (e.g., *DRD2*). Third, people who have low responsiveness (or low sensitivity) to alcohol are more likely to drink more on each occasion to obtain the desired effect, which increases their risk of alcohol-use disorders but not of other drug-related disorders. Additional genetic mechanisms might regulate dopamine-reward systems.

Table 185-1 Causes of Death Related to Alcohol Abuse

1	Mouth and oropharynx cancer

7	Falls
8	Intentional injuries

Modified from Miranda-Mendez A, Lugo-Baruqui A, Armendariz-Borunda J: Molecular basis and current treatment for alcoholic liver disease. Int J Environ Res Public Health 7:1872-1888, 2010.

Definition and Natural History

A precise definition of alcoholism is difficult. A proposed definition encompassing the features of alcoholism is "a primary chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations." The disease is often progressive and fatal. It is characterized by impaired control over drinking, preoccupation with and use of alcohol despite adverse consequences, and distortions in thinking, most notably denial. Each of these symptoms may be periodic or continuous.[8] Alcoholism is present when drinking adversely affects an individual's physical health, ability to function in society, or interpersonal relationships.

Hazardous or "at-risk" drinking is defined by the National Institute on Alcohol Abuse and Alcoholism as the following:

Table 185-2 Current Biomarkers in Alcoholism

MARKER	ABBREVIATION	HALF-LIFE/ELIMINATION RATE	CLINICAL CHARACTERISTICS
Blood ethanol	EtOH	1 g/1 h/10 kg	Levels exceeding 1.5% without evidence of intoxication or 3% at any time indicate ethanol tolerance typically found in alcohol abusers and alcohol-dependent patients. Suitable for emergency clinics
γ-Glutamyltransferase	GGT	2-3 weeks	A sensitive and inexpensive marker Age dependent Specificity decreased by obesity, diabetes, nonalcoholic liver diseases, pancreatitis, hyperlipidemia, cardiac insufficiency, severe trauma, medications (barbiturates, drugs for epilepsy, anticoagulants), nephrotic syndrome, renal rejection
Mean corpuscular volume of erythrocytes	MCV	2-4 months	More sensitive in women Specificity decreased by vitamin B_{12} or folic acid deficiency, liver diseases, hematologic diseases, hypothyroidism, reticulocytosis, smoking
Carbohydrate-deficient transferrin (desialotransferrin)	CDT	2-3 weeks	Most specific of the currently available methods Specificity decreased by genetic variants of transferrin on rare occasions
GGT-CDT combination	GGT-CDT (γ-CDT)	2-3 weeks	A mathematically formulated combination that is easy to manage in hospital laboratories Improves sensitivity without a loss of specificity Good correlation with the amount of recent ethanol intake Suitable for routine use
Aminotransferases	AST, ALT	2-3 weeks	AST/ALT ratio above 2 suggests alcoholic etiology in liver disease patients

From Niemelä O: Biomarkers in alcoholism. Clin Chim Acta 377:39-49, 2007.

www.ketabpezeshki.com 66485457-66963820

Table 185-3 Emerging Biomarkers in Alcoholism

MARKER	ABBREVIATION	HALF-LIFE/ELIMINATION RATE	CLINICAL CHARACTERISTICS
Acetaldehyde adducts	AA	Depends on carrier protein	Present in circulation and tissues of alcoholics Antigen for autoimmune responses Anti-adduct IgAs specific for alcohol abusers
5-Hydroxytryptophol	5-HTOL	14-15 hours	Measurements from urine Sensitive indicator of relapses 5-HTOL ratio to 5-hydroxyindole-3-acetic acid improves specificity
Ethyl glucuronide	EtG	3-5 days	Measurements from urine
Phosphatidylethanol	PEth	2 weeks	A specific metabolite of ethanol Sensitive to sample storage
Sialic acid	SA	2-5 weeks	Sensitive for alcohol abuse but lacks specificity May help differentiate between alcohol abuse and secondary effects of liver disease

From Niemelä O: Biomarkers in alcoholism. Clin Chim Acta 377:39-49, 2007.

Men: more than 14 drinks per week or more than 4 drinks per occasion
Women: more than 7 drinks per week or more than 3 drinks per occasion
Age older than 65 years: more than 7 drinks per week or more than 1 drink per occasion

Harmful drinkers present with negative consequences related to alcohol.

The natural history of alcoholism is variable, and it may appear in any patient despite age or social status. The age at onset of alcoholism continues to decrease. Up to 6% of high school seniors drink daily, and it is not unusual to see children younger than 16 years who have already graduated from an alcohol detoxification program.[9] Many individuals also begin drinking heavily after the age of 60 years.

The DSM-IV has two categories for substance disorders that include alcohol abuse: (1) substance abuse and (2) substance dependence.[7] The chronic *substance abuse* of alcohol eventually leads to *acquired tolerance,* a condition in which larger and larger doses of alcohol are required for the same effect.

PRINCIPLES OF DISEASE: METABOLISM OF ALCOHOL

Ethanol is rapidly absorbed from the stomach and small intestine. It is distributed uniformly to all organ systems, including the placenta. Although 2 to 10% of alcohol is excreted through the lungs, urine, and sweat, the majority is metabolized to acetaldehyde, primarily by alcohol dehydrogenase (ADH). The oxidation of alcohol is a complex process involving three enzyme systems, all contained in the hepatocyte. The class I ADH isoenzymes, ADH1A, ADH1B, and ADH1C, oxidize ethanol, but ADH1B and ADH1C have polymorphic properties with distinct kinetic properties. Acetaldehyde is then quickly converted to carbon dioxide and water, primarily through aldehyde dehydrogenase (ALDH). The common forms of ADH decrease the alcohol concentration in blood by about 4.5 mmol/L ethanol per hour (the equivalent of about one drink per hour).

$$\text{Ethanol} \xrightarrow[\text{NAD}\rightarrow\text{NADH}]{\text{Alcohol hydrogenase}}$$
$$\text{Acetaldehyde} \xrightarrow[\text{NAD}\rightarrow\text{NADH}]{\text{Alcohol dehydrogenase}}$$
$$\text{Acetyl coenzyme A} \xrightarrow[\text{Cycle}]{\text{Citric acid}} CO_2 + H_2O$$

At least two variations of ADH genes (*ADH1B*2* and *ADH1C*1*) produce a slightly more rapid breakdown of alcohol and therefore potentially faster production of acetaldehyde, which is rapidly metabolized by *ALDH2*. However, about 40% of Asian people (Japanese, Chinese, and Koreans) have an inactive *ALDH2* mutation that results in much higher acetaldehyde levels after drinking than normal. About 10% of people who are homozygous for this gene form cannot drink alcohol without becoming sick and have almost no risk of alcohol-use disorders, whereas those who are heterozygous have a relatively low rate of alcohol-use disorders.

An alternative pathway, the microsomal ethanol-oxidizing system (MEOS), is induced by chronic alcohol exposure. The primary component of the MEOS is the molecule cytochrome P_{450}, which exists in several variants. The variant most important for alcohol metabolism is cytochrome P_{450} 2E1 (CYP2E1). Many effects of alcoholism are produced by the toxic byproducts (hydrogen, acetaldehyde), the acceleration of metabolism of other drugs, and activation of hepatotoxic compounds by these metabolic pathways.

Although the liver is the major site of ethanol metabolism, other tissues contribute to its metabolism. ADH is found in the gastric mucosa, but the gastric metabolism of alcohol is decreased in women and those of Asian descent. This increased bioavailability of ethanol or decreased first-pass metabolism may explain the greater vulnerability of women to acute and chronic complications of alcohol.

Alcohol elimination has two phase curves. The alcohol elimination rate approximates zero-order kinetics (constant rate) for lower ethanol levels and first-order kinetics (amount of drug removed over time is proportional to the concentration of the drug) for higher levels, especially in chronic alcoholics; most likely, through induction of the MEOS pathway, the elimination rate is increased at higher blood levels.

The absorption and elimination rates of alcohol vary by individual and depend on many factors: diet, gender, body weight and habitus, speed of consumption, gastric motility, presence of food in the stomach, smoking history, age, whether the person is a chronic alcohol consumer with enzyme induction and high-activity MEOS, advanced cirrhosis, presence of ascites, and state of nourishment.[10] There is enormous variation among patients in the rate of disappearance of ethanol from the blood, ranging from 9 to 36 mg/dL per hour in published data. Although the clearance rate may be as high as 36 mg/dL per hour in some chronic drinkers, 20 mg/dL per hour is a reasonable rate to assume in a typical intoxicated ED patient. This holds true for adults, adolescents, and children.[11]

Physiologic effects vary directly with the blood alcohol level (Table 185-4). Diminished fine motor control and impaired judgment appear with alcohol concentrations as low as 20 mg/dL

www.ketabpezeshki.com 66485457-66963820

Table 185-4 Physiologic Effects and Blood Alcohol Levels

BLOOD ALCOHOL CONCENTRATION (mg/dL)	EFFECTS*
20-50	Diminished fine motor control
50-100	Impaired judgment; impaired coordination
100-150	Difficulty with gait and balance
150-250	Lethargy; difficulty sitting upright without assistance
300	Coma in the novice drinker
400	Respiratory depression

*These effects are for the occasional drinker. Chronic drinkers can function at much higher alcohol concentrations because of tolerance. On the other hand, patients may become comatose with low levels of alcohol in mixed alcohol-drug overdose.

(0.02 mg%), but wide individual variability exists. Chronic alcoholics can exhibit impressive tolerance. The blood alcohol concentration of a person cannot be accurately determined without quantitative testing. More than 50% of the adult population is obviously intoxicated with a level of 150 mg/dL (0.15 mg%). As the ethanol level rises, the patient's level of consciousness declines, eventually ending in coma. Death is caused by aspiration or respiratory depression.

Alcohol through passive diffusion will be present anywhere there is water in the body. Hence, expired breath alcohol or saliva can be used to obtain a reliable approximation of blood alcohol concentration in a cooperative patient. This value can be used as a rapid screen for alcohol intoxication.[12,13]

DIFFERENTIAL CONSIDERATIONS

Acute alcohol intoxication is a diagnosis of exclusion. Before it is assumed that a patient's behavior is caused only by alcohol, other conditions should be considered. Hypoglycemia, hypoxia, carbon dioxide narcosis, mixed alcohol-drug overdose, ethylene glycol poisoning, isopropanol or methanol poisoning, hepatic encephalopathy, psychosis, severe vertigo, postictal state, and psychomotor seizures can be manifested in a manner similar to ethanol intoxication. The possibility of occult head trauma and the presence of associated metabolic disorders should be considered after alcohol intoxication has been established. Shock from gastrointestinal bleeding or sepsis, hypothermia, hyperthermia, and hepatic encephalopathy are all possible. These potentially catastrophic diagnoses are usually detected by a thorough history and physical examination, a blood alcohol level (as coma is rare in chronically intoxicated patients with blood alcohol levels below 200 mg/dL), and close observation (an intoxicated patient's level of consciousness should constantly improve over time). Adequate history from paramedics and family, repeated physical examinations by the same clinician, and diagnostic adjuncts can help resolve this dilemma.

MANAGEMENT

Comatose or stuporous patients need to have airway and ventilation evaluated and managed with endotracheal intubation as necessary. Thiamine (100 mg intravenously [IV]) to prevent or to treat Wernicke-Korsakoff syndrome, glucose (dextrose, 25 to 50 g IV) for hypoglycemia, and naloxone (0.8 mg IV) for possible opioid ingestion should be considered in comatose patients. As magnesium is a necessary cofactor for thiamine metabolism, consider magnesium 2 g IV. When possible, hypoglycemia should be documented before the empirical administration of glucose. With the airway maintained and respirations supported, the patient's liver eventually metabolizes the alcohol, and most patients recover.

Glucose (dextrose, 25 g IV) produces a dramatic response in alcohol-induced hypoglycemic patients. Unlike hypoglycemia of other causes, alcohol-induced hypoglycemia may be unresponsive to glucagon because of depleted liver glycogen stores. Although Wernicke's encephalopathy is a medical emergency, alcohol-induced hypoglycemia is a much more common condition with serious and permanent morbidity if it is left untreated. Therefore, thiamine can be given in a timely fashion, but glucose therapy should not be delayed.[14]

Intoxicated patients require evaluation and treatment in the ED regardless of their obstreperousness. Inappropriate discharge and failure to diagnose are two common areas of liability in treatment of the alcohol-dependent patient. The theoretic liability for detention by reasonable restraint is less than the potential liability for injury sustained by the alcohol-dependent patient or an innocent bystander after premature discharge. Discharge can be considered when a patient is clinically sober and able to dress, walk, and function independently as judged and well documented by the treating clinician. Under ideal circumstances, another concerned, sober adult is available and willing to take responsibility for and remain with the patient for the next 24 to 48 hours.

ALCOHOL WITHDRAWAL SYNDROME

Principles of Disease

The neurophysiology of alcohol withdrawal is complex and not fully understood. Chronic alcohol consumption has a depressant effect on the central nervous system (CNS). The hallmark of alcohol withdrawal is CNS excitation with increased cerebrospinal fluid, plasma, and urinary catecholamine levels. Chronic alcohol consumption affects central adrenergic alpha receptors, glutamate, central adrenergic beta receptors, the inhibitory neurotransmitter γ-aminobutyric acid (GABA), and dopamine turnover.[15]

Differential Considerations

Alcohol withdrawal syndrome can initially be confused with acute schizophrenia, encephalitis, drug-induced psychosis, thyrotoxicosis, anticholinergic poisoning, and withdrawal from other drugs of the sedative-hypnotic type. It may be difficult to differentiate between alcohol withdrawal and alcohol-induced hypoglycemia.

Signs of alcohol withdrawal usually begin 6 to 24 hours after a decrease in the patient's usual intake of alcohol. If patients manifest withdrawal 3 to 4 days or more after their last drink, drugs with a longer half-life should be considered. The barbiturate and benzodiazepine withdrawal syndromes usually progress more slowly, with a higher frequency of seizures later (7 days versus 2 days), and status epilepticus is more common than with alcohol withdrawal.

Clinical Features

Isbell's classic study in 1955 confirmed the relationship between alcohol and the withdrawal syndrome.[16] He documented that the severity of signs and symptoms depends on both the dose and the duration of ethanol consumption. The withdrawal syndrome may occur any time after the blood alcohol level starts to fall. Therefore, only a reduction, not the abrupt cessation, of ethanol intake may result in withdrawal.

Minor alcohol withdrawal occurs as early as 6 hours and usually peaks at 24 to 36 hours after cessation of or significant decrease in alcohol intake. It is characterized by mild autonomic hyperactivity: nausea, anorexia, coarse tremor, tachycardia, hypertension,

www.ketabpezeshki.com 66485457-66963820

hyper-reflexia, sleep disturbances (e.g., insomnia, vivid dreams), and anxiety.[17]

Major alcohol withdrawal occurs after more than 24 hours and usually peaks at 50 hours but occasionally takes up to 5 days to be manifested after the decline or termination of drinking. The syndrome is characterized by pronounced anxiety, insomnia, irritability, tremor, anorexia, tachycardia, hyper-reflexia, hypertension, fever, decreased seizure threshold, auditory and more commonly visual hallucinations, and finally delirium.[18]

Delirium tremens is a life-threatening manifestation of alcohol withdrawal and consists of gross tremor, frightening visual hallucinations, profound confusion, agitation, and a hyperadrenergic syndrome characterized by temperature above 101° F, blood pressure higher than 140/90 mm Hg, and tachycardia. It seldom appears before the third post-abstinence day. Only 5% of patients hospitalized for alcohol withdrawal have delirium tremens.

Management

Family, friends, bystanders, or paramedics often give more reliable historical data than the patient does. Accurate vital signs are essential. This may require a rectal temperature. Hyperthermia, hypothermia, tachypnea, or tachycardia may suggest serious disorders that often accompany the alcohol-dependent patient. These disorders should be considered during this first assessment.

A rapid, thorough examination should be performed with attention to the level of consciousness, signs of hepatic failure, or coagulopathy. Signs of trauma are sought, such as subcutaneous emphysema, ecchymosis, subconjunctival hemorrhage, hemotympanum, or Battle's sign, and palpation is done for occult injuries. The neurologic examination should search for focal findings, including central facial nerve palsy, hemiparesis, and asymmetry of pupillary response.

The alcohol withdrawal syndrome should be promptly recognized and treated to provide relief from anxiety and hallucinations; to halt progression to major withdrawal and withdrawal seizures; to allow detection of a treatable primary psychiatric illness; to prepare the patient for long-term alcohol abstinence with the lowest risk of new drug dependence; and to calm the patient and allow adequate examination for the detection of medical illnesses that typically accompany alcoholism, such as gastritis, dehydration, pancreatitis, pneumonia, electrolyte disorders, and hepatitis.

In combination with appropriate chemical sedation, detention by reasonable restraint may be an option to prevent potential injury that patients may inflict on themselves or the hospital staff. These appropriate measures need to be instituted, and decision-challenged patients should not be permitted to sign an "against medical advice" form and be discharged.

Patients suffering from alcohol withdrawal should receive pharmacologic intervention along with supportive care. The ideal drug for alcohol withdrawal would have a rapid onset, wide margin of safety, metabolism not dependent on liver function, and limited abuse potential. Although no one drug class fits all these requirements, benzodiazepines are clearly the mainstay of treatment.

Benzodiazepines. The benzodiazepines have superior anticonvulsant activity, have the least respiratory and cardiac depressive effect of all the CNS depressants, and can be given parenterally in the uncooperative patient. By interacting with receptors linked to the GABA-associated chloride ion channel, benzodiazepines substitute for the withdrawal of the GABA-potentiating effect of alcohol and abate withdrawal signs and symptoms.[19] Numerous benzodiazepines have been studied, but there is no evidence of clear superiority of any one benzodiazepine.

Lorazepam has good bioavailability with oral, intramuscular, and intravenous routes. It is rapidly and completely absorbed from intramuscular sites in agitated patients with no intravenous access. Lorazepam's half-life is intermediate (7-14 hours), and it reaches a steady state in 36 to 48 hours without active metabolites. Excessive sedation, confusion, and ataxia are potential complications of all benzodiazepines with prolonged half-lives. Lorazepam is metabolized (conjugated) in the liver, yielding inactive products. Although the half-life of lorazepam increases in patients with cirrhosis or liver failure, it is much less than the increase with chlordiazepoxide. Lorazepam's elimination is only minimally altered in patients with renal failure and in the elderly. Lorazepam may be given intravenously in a dose of 1 to 4 mg, depending on the severity of the withdrawal. Dosing can be repeated at 5- to 15-minute intervals for patients in severe withdrawal. Although it is not ideal, an intramuscular dose of 1 to 4 mg can be used every 30 to 60 minutes until the patient is calm and then every hour as needed for light somnolence. The oral schedule for moderate withdrawal is 6 mg/day in three divided doses, tapering the amount by 1 to 2 mg/day during 4 to 6 days.

As one dosing regimen, diazepam, 5 mg IV every 5 to 10 minutes (2.5 mg/min), can be given in major withdrawal until the patient is calm. The dose can be repeated in 5 to 10 minutes. If the second dose of 5 mg is not working, consider 10 mg for the third and fourth doses every 5 to 10 minutes. If this is not effective, consider 20 mg for the fifth and subsequent dose until adequate sedation is obtained.[20,21]

Butyrophenones. Haloperidol, a dopamine antagonist, can be considered in patients with major alcohol withdrawal or delirium tremens not responding to intravenous benzodiazepines. Haloperidol has little effect on myocardial function or respiratory drive, and its safety and efficacy by the intravenous, intramuscular, or oral route in the ED have been established. Haloperidol has no anticonvulsant properties; however, extrapyramidal effects may be seen. Caution should be used in patients who may be susceptible to a prolonged QTc. Droperidol has effects similar to those of haloperidol. Despite the 2001 Food and Drug Administration black box warning for QTc prolongation and torsades de pointes after droperidol use, droperidol remains a safe and effective treatment for agitated patients.[22]

Emergency Department and Outpatient Approaches

Outpatient treatment consists of lorazepam, 1 to 2 mg three times a day in a tapering dose for 3 to 6 days; chlordiazepoxide, 25 to 100 mg three times a day, in a tapering dose for 3 to 6 days; or diazepam, 30 mg once a day tapered during 5 days, depending on the severity of symptoms. Adequate diet, abstinence, and participation in a rehabilitation program in the community are also desirable. Any patient requiring 300 mg of chlordiazepoxide or 60 mg of diazepam per day to control withdrawal should be considered for admission. Patients with major alcohol withdrawal (disorientation, hallucinations, diaphoresis, or fever) are admitted.

Adjunctive Therapy

Patients being treated for major alcohol withdrawal may be given thiamine (100 mg IV) and magnesium (2 g IV). Although magnesium sulfate does not decrease the severity of withdrawal symptoms, the incidence of delirium, or seizures, it carries no significant risk (with adequate renal function).

If volume depletion is present, it can be corrected with normal saline. Reversal of electrolyte and metabolic disorders (hypomagnesemia, hypophosphatemia, hypokalemia, and acidosis) benefits the patient, but it does not abate the withdrawal syndrome.

ALCOHOL-RELATED SEIZURES

Among the many medical problems related to alcohol abuse, the differential diagnosis and management of seizures remain among

www.ketabpezeshki.com 66485457-66963820

Box 185-1 Differential Diagnosis of Alcohol-Related Seizures

Withdrawal (alcohol or drugs)
Exacerbation of idiopathic or post-traumatic seizures
Acute intoxication (amphetamines, anticholinergics, cocaine, isoniazid, organophosphates, phenothiazines, tricyclic antidepressants, salicylates, lithium)
Metabolic (hypoglycemia, hyponatremia, hypernatremia, hypocalcemia, hepatic failure)
Infectious (meningitis, encephalitis, brain abscess)
Trauma (intracranial hemorrhage)
Cerebrovascular accident
Sleep deprivation
Noncompliance with anticonvulsants

the most challenging and controversial (Box 185-1). Patients presenting to the ED with seizures should be questioned about alcohol intake. Of seizure patients presenting to an ED, 20 to 40% will have their seizures related to alcohol use or abuse.[23] Alcohol is a causative factor in 11 to 24% of patients with status epilepticus.[24,25] In states where alcohol sales are restricted on Sundays, EDs see a spike in alcohol-related seizures on Mondays.[26]

The primary consideration in the initial care of seizure patients who use alcohol is the recognition of treatable, life-threatening causes. These causes include but are not limited to CNS infection, metabolic disorders, and intracranial hemorrhage. Alcohol may act in one of several ways to produce seizures in patients with or without underlying foci: by its partial or absolute withdrawal after a period of chronic intake, by an acute alcohol-related metabolic disorder (e.g., hypoglycemia, hyponatremia), by creation of a situation leading to cerebral trauma, by precipitation of seizures in patients with idiopathic or post-traumatic epilepsy, or by lowering of the seizure threshold in patients with prior existing intracerebral disease states. Moreover, alcoholics are more susceptible to other disorders associated with seizures, including neurosyphilis, acquired immunodeficiency syndrome (AIDS), brain abscess, and meningitis.[27-29]

Alcohol Withdrawal Seizures

Descriptions of alcohol withdrawal seizures are based on data collected by Victor and Brausch.[30] Seizures occurred 6 to 48 hours after the cessation of drinking. Ninety percent had one to six generalized tonic-clonic seizures. Sixty percent experienced multiple seizures within a 6-hour period. However, seizure recurrence can be reduced to 3% with lorazepam administration after the initial seizure.[31] The incidence of partial seizures, common with post-traumatic epilepsy, is increased in alcohol withdrawal. The term *alcohol withdrawal seizure* is reserved for seizures with the characteristics described by Victor and Brausch.[30] The term *alcohol-related seizure* is used to refer to all seizures in the aggregate associated with alcohol use, including this subset of alcohol withdrawal seizure.

Patients Presenting with Normal Findings on Neurologic Examination

New-Onset Alcohol-Related Seizures

Patients with new-onset alcohol-related seizure should be thoroughly evaluated. This includes alcoholics who claim to have had seizures but for whom no documentation or an appropriate work-up is available. Metabolic disorders, toxic ingestion, infection, and structural abnormalities should be considered. Laboratory and radiographic testing to include electrolyte values and blood urea nitrogen, creatinine, glucose, and anticonvulsant levels and brain computed tomography (CT) scan may be necessary. Of 259 patients presenting with their first alcohol-related seizure, clinical management was changed in 3.9% on the basis of head CT results.[32]

If the initial physical examination findings, imaging studies, and laboratory test results are within normal limits, patients who remain seizure free and symptom free with no sign of withdrawal after 4 to 6 hours of observation may be discharged. It may be unclear whether the patient has had a pure alcohol withdrawal seizure or a new-onset seizure disorder in the setting of alcohol ingestion. Long-term treatment with antiepileptic drugs is not useful in unprovoked new-onset seizures that have resolved or when a clear relation to alcohol consumption can be identified.

Optimal outpatient treatment includes follow-up and referral to a detoxification or rehabilitation program. Ideally, the help of a concerned family member or friend who is not a drinking partner and can remain with the patient for at least 1 or 2 days is helpful.

Seizures in the Alert Patient with a History of Seizures during Prior Withdrawal

The risk of seizure increases significantly in alcoholic patients with manifestations of alcohol withdrawal who relate a history of alcohol withdrawal seizure.[33,34] Detoxification with benzodiazepines reduces alcohol withdrawal seizure and should be initiated early because most seizures occur within the first 24 hours after alcohol withdrawal. An initial dose of 2 mg of lorazepam or 5 mg of diazepam can be given intravenously. These doses frequently need to be repeated.[35] The patient should be observed for 4 to 6 hours before discharge is considered. The prescription of benzodiazepines or antiepileptic drugs on discharge carries its own hazards. Benzodiazepines (other than a short 3- to 6-day tapering dose for withdrawal) may increase the potential risk of addiction. In a noncompliant patient, antiepileptic drugs, such as phenytoin, may paradoxically increase the number of seizures. The poorly compliant alcoholic patient may do better without outpatient anticonvulsants for a concurrent seizure disorder.[33] The ideal disposition is referral to a detoxification or rehabilitation unit.

Patients with an Abnormal Neurologic Presentation

New-Onset Partial Seizures

Partial seizures account for 24 to 51% of alcohol-related seizures.[36] Conversely, studies have shown that 17 to 21% of patients with partial alcohol-related seizure have structural lesions: hematomas, tumors, vascular abnormalities, or stroke.[37] These primary causes of partial alcohol-related seizure, such as prior head trauma, may be easily missed in the history taking. As a result, an emergent CT scan is indicated to evaluate new-onset partial seizures. The patient with a history of a focal alcohol-related seizure who has been previously evaluated does not require an emergency CT scan, provided a return to baseline occurs promptly. A patient presenting with a focal alcohol-related seizure with subsequent normal neuroimaging findings can be managed with supportive care, observation for 4 to 6 hours, and a benzodiazepine for withdrawal signs or symptoms. Appropriate follow-up should be arranged.

Obtundation

The obtunded or stuporous alcohol-dependent patient with a history of seizure activity poses a diagnostic challenge. The patient's decreased level of consciousness may be the result of a postictal state, occult head trauma, unrecognized metabolic

www.ketabpezeshki.com 66485457-66963820

disorder, or other poisoning. The first diagnostic task is quickly to determine the possibility of hypoglycemia (diagnosed and reversed at the bedside in minutes) and to evaluate for other metabolic and toxic causes of altered mental status. Patients with an acute alteration in mental status should undergo a head CT scan if they are not demonstrating expected and obvious improvement.

Patients Taking Phenytoin-Anticonvulsant

Phenytoin has no significant benefit over placebo in prevention of recurrence of uncomplicated (e.g., no old subdural) alcohol withdrawal seizure. Considering the risks of phenytoin and no demonstrated benefit in the setting of alcohol withdrawal seizure, it is not indicated for the treatment of alcohol withdrawal seizure. The sudden withdrawal of phenytoin may potentiate the convulsive effects of alcohol withdrawal.[23,38]

A patient currently taking antiepileptic drugs for an antecedent seizure disorder who presents with a seizure while intoxicated falls into a different category. Such an episode could be an isolated event in a usually compliant patient without a history of chronic alcohol abuse. In this patient, a seizure in the setting of a subtherapeutic antiepileptic drug level may represent the consequences of noncompliance with antiepileptic medication or sleep deprivation versus alcohol withdrawal seizure.[33]

OTHER CLINICAL FEATURES AND MANAGEMENT

Cardiovascular Effects

Acute and chronic ethanol consumption can affect the mechanical function of the heart, produce dysrhythmias, and exacerbate coronary artery disease (CAD). It may alter myocardial function by direct toxic effects, by associated hypertension, or indirectly by altering specific electrolytes. Acute intoxication can decrease cardiac output in both alcoholic and nonalcoholic patients with preexisting cardiac disease.[38]

Studies have linked moderate alcohol consumption (two to four drinks per day in men and one or two in women) to a protective effect from CAD. Low to moderate alcohol consumption decreases platelet aggregation, raises plasma levels of endogenous tissue plasminogen activator,[39] and lowers insulin resistance. Experimental data suggest that alcohol may have antioxidant properties, produce effects on smooth muscles through interactions with nitric oxide, and alter plasma total homocysteine levels.[40,41] The red versus white wine hypothesis rests on human studies showing short-term cardiovascular benefits achieved by de-alcoholized red but not white wine and many studies on isolated tissues or organs assessing the effects of polyphenols in red wine, especially resveratrol. Therefore, red wine potentially has beneficial effects beyond alcohol content.[42]

Studies suggest that moderate alcohol consumption, through a reduced risk of CAD, may also protect individuals from congestive heart failure (Box 185-2).[43] All of these beneficial effects are lost in heavy drinkers, in whom chronic alcoholism is associated with hypertension and congestive cardiomyopathy.

Up to one third of chronic alcoholic patients have left ventricular dysfunction demonstrated by radionuclide ventriculography, usually coexisting with skeletal muscle disease. Those who stop using alcohol may have an improved ejection fraction during the course of 3 years.[44] Although the primary functional abnormality of alcoholic cardiomyopathy was thought to be a depression in systolic function, it is now appreciated that an impairment in diastolic function is present in one third of alcoholics who have a normal systolic function; in many, systolic dysfunction and diastolic dysfunction coexist. Excess alcohol consumption affects not only the cardiomyocytes but striated skeletal muscle as well. Women appear to be more sensitive than men to the toxic effects of alcohol on striated muscle and are at greater risk for cardiomyopathy and myopathy as well as for skeletal myopathy for any given lifetime amount of alcohol.[44]

Heavy alcohol consumption has a detrimental effect on those with preexisting CAD. It can reduce exercise tolerance, induce coronary vasoconstriction, and raise heart rate and blood pressure.[45] Additive cardiovascular effects of ethanol and nicotine contribute to dysrhythmias and sudden death in patients with CAD. In one study, nearly half the patients with alcohol withdrawal had prolongation of the QT interval. Prolonged QT can precipitate a dysrhythmia, resulting in sudden death.[46] There is an increased incidence of sudden death among heavy drinkers regardless of concomitant CAD or smoking.

Supraventricular (usually atrial fibrillation) and ventricular (usually transitory ventricular tachycardia) dysrhythmias, labeled "holiday heart," have been documented in alcoholic patients who have been drinking heavily. One study reported that alcohol contributes to or causes new-onset atrial fibrillation in approximately two thirds of patients younger than 65 years. Tachydysrhythmias as a result of episodic drinking commonly revert to sinus rhythm with abstinence and do not require immediate intervention if the patient is hemodynamically stable.

Alcohol also affects cardiac function indirectly by lowering potassium and magnesium levels. Data from the Framingham Heart Study indicate that patients with lower levels of potassium and magnesium have higher rates of dysrhythmias.[47]

Pulmonary Effects

Alcohol reduces the mobilization of alveolar macrophages and their bactericidal capacity. Their impairment is greatest in alcoholics with hepatic cirrhosis. In alcoholic patients, the lungs are more vulnerable to oxidative stress and injury. There is evidence that chronic alcohol consumption decreases the level of glutathione, promoting inflammation and remodeling of the lung tissue.[48] These effects, along with aspiration, decreased airway sensitivity, concomitant smoking, and malnutrition, probably account for the increased incidence of pneumonia, particularly lobar pneumonia, among alcoholic patients.[49] Alcohol abuse is also associated with an increased likelihood of intensive care unit admission and a longer hospital length of stay than for non-alcoholic patients with community-acquired pneumonia.[50]

At least 80% of alcoholics are smokers, making it difficult to distinguish between alcohol-induced and tobacco-induced injury to the lungs. The high prevalence of respiratory disease in alcoholics is largely caused by smoking. Patients with sepsis and chronic alcohol abuse are at least twice as likely to require mechanical ventilation and have a twofold to fourfold risk for development of the acute respiratory distress syndrome.[50]

Alcohol induces bronchospasm in some asthmatics and increases ventricular ectopy and sleep apnea in patients with chronic obstructive pulmonary disease. Alcoholic patients with hepatic cirrhosis can have hypoxemia as a result of precapillary shunting in their lungs. Hyperventilation and respiratory alkalosis are also seen with hepatic cirrhosis. One or two drinks per day has been found to decrease the risk of pulmonary embolus and deep venous thrombosis in elderly patients.[51]

Gastrointestinal and Hepatic Effects

Esophagus and Stomach

Alcoholic patients have a higher incidence of esophagitis, gastric cancer, and esophageal carcinoma than that in the general population. Acute alcohol ingestion also decreases lower esophageal sphincter pressure, delays gastric emptying, and disrupts the

normal gastric mucosal barrier. Alcohol consumption, because of its inherent toxicity, has been shown to eliminate infection of the gastric mucosa by *Helicobacter pylori*.[52] Vomiting is common among drinkers. Forceful or persistent emesis can lead to a Mallory-Weiss tear or Boerhaave's syndrome.

Gastrointestinal Bleeding

Alcohol is closely associated with gastrointestinal bleeding. Causes and contributing factors include Mallory-Weiss tears, esophagitis, esophageal varices, acute and chronic gastritis, thrombocytopenia, portal hypertensive gastropathy, qualitative and quantitative platelet disorders, and prolonged clotting times. Alcohol may exacerbate gastric mucosal damage when it is combined with non-steroidal anti-inflammatory drugs (NSAIDs), but ethanol itself is not a risk factor for peptic ulcer disease. An inverse relationship exists between consumption of alcohol, particularly wine, and active *H. pylori* infection. Peptic ulcer disease is the most common cause of bleeding in alcoholic patients with upper gastrointestinal hemorrhage as well as in those who do not drink.[53]

Liver

Hepatic damage has been recognized for centuries as the hallmark of chronic alcohol abuse. Obesity potentiates the severity of alcohol-induced liver damage.[54] The activation of the immune system with the production of cytokines such as tumor necrosis factor alpha is one of the earliest events in many types of liver injury.[55] This cascade stimulates Kupffer cells and the production of other cytokines that together enlist inflammatory cells, kill hepatocytes, and initiate healing through fibrogenesis. There is no single test that can be used to diagnose alcoholic liver disease reliably. However, the ratio of AST to ALT higher than 2 suggests that alcohol is the cause of liver injury.[56] Alcoholic liver disease is the most common liver disorder in the Western world and along with hepatitis C is a leading cause of liver transplantation.[57]

The earliest, mildest, and most common liver change in alcoholism is the accumulation of macrovesicular fat in the hepatocytes, predominantly involving triglycerides. Alcoholic fatty liver is usually asymptomatic, associated with mild elevations of AST and ALT. It is detected by the finding of hepatomegaly on physical examination or abnormalities on ultrasonography or CT but is confirmed by liver biopsy. Fatty liver is a reversible disorder if the patient can refrain from drinking.[58]

Alcoholic Hepatitis

Alcoholic hepatitis is more serious than fatty infiltration and develops in up to 35% of heavy drinkers.[59] These individuals usually have right upper quadrant pain, tender enlarged liver, fever, jaundice, leukocytosis, and altered liver function test results. AST levels are usually less than 400 IU/L, and ALT levels are typically less than half the AST level. Alcoholic hepatitis has a range of clinical manifestations, from mildly symptomatic hepatomegaly to fulminant hepatic failure. The severity of the disease can be estimated in the ED by a prolonged prothrombin time/international normalized ratio (INR)[60] or with the use of discriminant factor.[61] The ABIC (age, bilirubin, INR, creatinine) score and the Model for End-stage Liver Disease (MELD) are also helpful in predicting mortality in these patients.[59,62]

Evaluation of symptomatic patients includes complete blood count, electrolyte values, blood urea nitrogen and creatinine concentrations, glucose concentration, prothrombin time/INR, liver function tests, and urinalysis. If the patient has an abnormal prothrombin time/INR and is actively bleeding, fresh frozen plasma should be started in the ED. Steroids are indicated in severe cases (encephalopathy, coagulopathy).[63] Steroids are relatively contraindicated in patients with gastrointestinal bleeding or concurrent infection. In those for whom steroid treatment is contraindicated, pentoxifylline has been shown to be beneficial.[64] Up to 80% of patients with alcoholic hepatitis who continue to drink eventually have cirrhosis.

www.ketabpezeshki.com 66485457-66963820

Alcoholic Cirrhosis

Cirrhosis is the disruption of the normal architecture of the liver by scarring and regenerating nodules of parenchyma. Alcoholism is the most common cause of cirrhosis in the United States and is responsible for approximately 50% of all cirrhotic deaths. Alcoholic cirrhosis usually requires 10 to 15 years of chronic drinking, often punctuated by one or more episodes of acute alcoholic hepatitis. The clinical outcome is determined by the development of complications of portal hypertension and by hepatic dysfunction. It is unknown why hepatic damage develops in some alcoholic patients and not in others exposed to identical amounts of alcohol. The disorder was originally described as "nutritional cirrhosis," but it has been shown that alcohol, independent of malnutrition, produces the liver damage. Alteration of the normal hepatic architecture by fibrosis and nodule formation may eventually lead to portal hypertension. Portal hypertension may be complicated by ascites and esophageal varices. Although cirrhosis is irreversible, its progression may be halted with abstinence.

Hepatitis C antibodies are found in one third to one half of alcoholics with alcoholic liver disease, presumably from similar risk factors. Patients with alcoholic liver disease and hepatitis C have histologically more severe disease, shorter survival, and tenfold increased rates of cirrhosis and liver cancer.[65]

No specific medical therapy exists for alcoholic liver disease other than abstinence, proper diet, and management of the subsequent hepatic decompensation (i.e., ascites and encephalopathy). A decrease in the amount of alcohol consumed during 1 year is associated with a 60% decrease in mortality.[66]

Pancreatitis and Malabsorption

The association of ethanol with both acute and chronic pancreatitis is well established, but the exact pathogenesis is unclear. Hypotheses include reflux of duodenal contents and bile into the pancreatic duct, obstruction by a plug of pancreatic juice rich in proteins, and direct toxic effect of ethanol.

The diagnosis of alcoholic pancreatitis can be difficult because asymptomatic alcoholics may have an elevated amylase level. Conversely, up to 30% of patients with acute alcoholic pancreatitis have an amylase value within normal limits. Serum lipase rises after amylase, remains elevated longer, and is a more reliable indicator of alcoholic pancreatitis, especially when it is more than three times normal.[67] Alcohol is the leading cause of chronic pancreatitis.

Diarrhea and impaired intestinal absorption are common problems of the chronic alcoholic. Alcohol increases small intestine transit time and decreases brush border enzyme activity. Thiamine, vitamin B_{12}, amino acids, folic acid, and glucose have impaired absorption in alcoholics. Dietary deficiencies in folic acid and protein, pancreatic insufficiency, abnormal biliary secretion, and direct toxic effects of ethanol on the gastrointestinal tract contribute to malabsorption. Abstinence and adequate nutrition reverse the diarrhea and much of the malabsorption.[58]

Neurologic Effects

Neuropathy

A symmetrical sensorimotor polyneuropathy is common with chronic alcohol abuse, usually in the lower extremities. It is thought to be a combination of nutritional deficiency with thiamine or B_{12} deficit and a direct neurotoxic effect of alcohol. Burning pain and paresthesia are common complaints. Findings on physical examination include loss of light touch, decreased pinprick sensation, and reduced lower extremity deep tendon reflexes. Distal muscle weakness is a late finding. The neuropathy may lead to nonhealing ulcers on the feet. Treatment of alcoholic neuropathy is abstinence, adequate diet, and thiamine. Complete recovery is rare.

"Saturday night palsy" or "honeymooner's syndrome" is a wrist drop caused by radial nerve compression. The patient usually has spent the night with the arm drooped over the back of a chair, bench, or a companion, compressing the radial nerve against the humerus and producing a neurapraxia. Loss of function due to radial nerve neurapraxia usually returns after a few weeks to months.

Wernicke-Korsakoff Syndrome

Although they are similar pathologically and caused by thiamine deficiency, Wernicke and Korsakoff syndromes are clinically distinct. Wernicke's encephalopathy, a medical emergency with a mortality rate of 10 to 20%, remains a clinical diagnosis and is often unrecognized. Contemporary criteria require two of these signs: dietary deficiencies, oculomotor abnormalities (nystagmus is most common), cerebellar dysfunction, and either an altered mental state or mild memory impairment.[68] Mental abnormalities include lethargy, inattentiveness, abulia, and impaired memory, progressing without treatment to coma.

Genetic and environmental factors may play a part in the pathogenesis of this disorder. A thiamine-dependent enzyme, transketolase, is deficient or less active in some patients who have Wernicke-Korsakoff syndrome. This may explain why the disorder develops in only a few alcoholics. Persons with transketolase deficiency are asymptomatic until they are stressed by thiamine deficiency. Protracted vomiting, inadequate diet, and malabsorption contribute to thiamine deficiency in the alcoholic.[69]

Korsakoff's psychosis or amnesic state, also called alcohol-induced persisting amnestic disorder, is a disorder with recent memory impairment, inability to learn new information or to recall previously learned information, apathy, and confabulation. Although it is common, confabulation is not essential for the diagnosis. Whereas 80% of patients with acute Wernicke's encephalopathy have Korsakoff's syndrome, age older than 40 years and many years of heavy alcohol use are additional risk factors.[70]

Treatment of Wernicke-Korsakoff syndrome consists of abstinence, adequate diet, and thiamine. The ophthalmoplegia and nystagmus usually have a good response to thiamine within hours to days. The ataxia and mental changes may take days to weeks to improve and usually have a poorer prognosis. Less than 25% of patients show any real recovery, 50% show some recovery, and the remainder show no response despite adequate thiamine replacement. Because magnesium is a cofactor for this enzyme system, serum levels should be corrected. Patients with Wernicke's syndrome require admission and aggressive thiamine and magnesium repletion.

Movement Disorders

Alcohol withdrawal is associated with tremor, ataxia, and myoclonus. Acute alcohol consumption ameliorates essential tremor and myoclonus. Persistent tremor is occasionally seen in chronic alcoholism. This alcoholic tremor may persist up to 1 year after abstinence. Although the pathophysiologic mechanism is poorly understood, studies have confirmed that essential tremor and alcoholic tremor are distinct entities.[71]

Alcoholic Cerebellar Degeneration

Characterized by ataxia of the extremities, cerebellar ataxia of alcoholism results in a wide-based stance and uncoordinated gait. Lower extremity involvement predominates, although the arms may rarely be involved. Pathologic changes consist of degeneration

www.ketabpezeshki.com 66485457-66963820

of elements in the cerebellum, especially the Purkinje cells. The diagnosis is based on history, physical examination, and magnetic resonance imaging or CT (which shows severe cerebellar atrophy). Treatment consists of abstinence, adequate nutrition, and thiamine.[72]

Dementia

Some studies suggest that ethanol may offer direct neuroprotection to the brain, bearing on the apparent risk reduction of dementia in selected drinkers.[73] Once again, a J-shaped curve emerges, with moderate intake reducing the risk of cognitive impairment and heavy drinking increasing it.[74] Whereas small amounts of ethanol probably protect against dementia and Alzheimer's disease but not against vascular dementia or cognitive decline, these conclusions are controversial.[75]

Infections

Experimental and clinical data support the conclusion that alcohol is a potent immunomodulatory agent. Chronic alcohol abuse (≥8 drinks/day) leads to immunosuppression.[76] Animal and human studies have implicated acute and chronic ethanol ingestion in causing decreased serum bactericidal activity, impaired mononuclear phagocyte function, diminished cell-mediated immune functions, reduced delayed hypersensitivity reaction, and defective polymorphonuclear neutrophils. Neutropenia may be found in up to 8% of hospitalized alcoholics.[77]

Alcohol ingestion prevents the normal delivery (chemotaxis) of polymorphonuclear neutrophils to sites of bacterial infection. Chronic alcohol exposure depresses the development and expression of cell-mediated immunity. This depression may contribute to the high incidence of tuberculosis and head, neck, and upper gastrointestinal cancers in alcoholics. Alcohol's suppression of macrophage function reduces the reticuloendothelial system's ability to clear particles. This may contribute to spontaneous bacteremia, spontaneous bacterial peritonitis, and pneumonia. Primary antibody response to new antigens is also depressed. Malnutrition and liver failure also contribute to an immunocompromised state in the alcoholic.

The most common infection in alcoholism is pneumonia. Associated risk factors for pneumonia in alcoholics include smoking, decreased ciliary function, decreased surfactant production, depressed cough reflex, malnutrition, and poor oral hygiene. Although alcoholic patients may contract a variety of bacterial pneumonias, *Streptococcus pneumoniae* is still the most common organism. Periods of alcoholic stupor with incomplete glottic closure and subsequent aspiration can lead to aspiration pneumonia or lung abscess. *Klebsiella pneumoniae,* classically associated with alcoholism, is currently more common in patients with cytotoxic chemotherapy, hematologic malignant disease, and transplantation than in the chronic alcoholic. In addition, these infections now tend to be nosocomial rather than community acquired.[77]

Chronic alcoholism is also associated with a threefold increase of tuberculosis.[78] Alcoholism itself does not seem to influence the long-term relapse rates in tuberculous patients if they have closely supervised therapy of adequate duration. Homeless alcoholic patients are an important reservoir of tuberculosis in the United States.

Spontaneous bacterial peritonitis occurs in cirrhotic patients with ascites and has a high mortality rate (50-90%). A common presentation consists of fever, abdominal pain, and leukocytosis. *Escherichia coli, K. pneumoniae,* and *S. pneumoniae* are the most common bacteria cultured from the ascitic fluid. Patients with new ascites and fever should have a diagnostic paracentesis as part of their evaluation.

Hepatitis C appears to be related to concomitant injection drug use rather than the direct effect of alcohol abuse. Alcoholism is associated with a high prevalence of unsafe sexual behavior and human immunodeficiency virus (HIV) seropositivity,[79] with greater immunologic changes in HIV-1–positive patients who also consume alcohol.[80]

Fever in the chronic alcoholic may result from a vast array of causes. The most common infection remains pneumonia. Occult urinary tract infections are more common than expected. The most common noninfectious causes of fever are alcohol withdrawal and alcoholic hepatitis. A leukocytosis is associated with both, often making the differentiation from infection difficult. Both infectious and noninfectious causes may coexist, and there may be multiple sources of infection. Most febrile alcoholics without an identifiable source are best served by hospitalization.

Endocrine Effects

Alcohol dependence adversely affects many endocrine systems. Both peripheral thyroid hormone dysfunction and central hypothalamic-pituitary-thyroid axis deregulation are seen.[81] Male hypogonadism and feminism are seen in chronic male alcoholics. Alcohol's effects on both the testes and the hypothalamus decrease testosterone production in men.[82] Alcohol may cause impotence by CNS sedation, secondary depression, or decreased testosterone production. Decreased testosterone, increased estrogen (in patients with liver disease), and increased prolactin can lead to decreased libido, feminization, and gynecomastia in male alcoholics and to abnormalities in lactation and menstruation in women. In female alcoholics, increased levels of testosterone and estrogen are found. Estrogen replacement therapy may increase hormonal levels threefold and thus increase the risk of cholelithiasis and breast cancer.[83]

Metabolic Effects

Carbohydrates

Alcohol-induced hypoglycemia occurs in 1 to 4% of intoxicated ED patients. It is more frequently seen in chronic alcoholics.[84] Coma, seizures, hemiparesis, and a variety of other neurologic signs have been described in patients presenting with alcohol-induced hypoglycemia. Starvation, depletion of liver glycogen stores, decreased plasma cortisol levels, impaired release of growth hormone, and inhibition of gluconeogenesis contribute to this phenomenon.

Hyperglycemia and diabetes may be found in chronic alcoholism. Alcohol abuse can lead to chronic pancreatitis, resulting in underproduction of insulin by the damaged pancreatic cells. Alcohol also impairs peripheral glucose utilization, causing a relative insulin resistance (similar to type 2 diabetes). In diabetic patients, alcohol can induce hypoglycemia and also mask the signs of hypoglycemia. This is more prominent in the fasting state.[85]

Lipids

A reversible hypertriglyceridemia occurs in many chronic alcoholics. Ethanol increases hepatic synthesis of triglycerides. Abstention is necessary to reduce elevated triglyceride levels. Except for its relationship to fatty infiltration of the liver, the clinical significance of this hyperlipidemia is unknown.[86]

Electrolytes

Ethanol has numerous effects on electrolytes and mineral metabolism as summarized in Table 185-5. Hyponatremia and hypokalemia are common in active drinkers. Vomiting, diarrhea, magnesium

depletion, malnutrition, and metabolic alkalosis contribute to these abnormalities.

Alcoholism is the most common cause of severe magnesium deficiency in adult outpatients. Thirty percent of alcoholics are magnesium deficient as a result of malabsorption, malnutrition, diarrhea, vomiting, and increased urinary losses. Oral magnesium supplementation in chronic alcoholics improves liver function test findings, electrolyte balance, and muscle strength.[87] Multivitamin preparations may be considered for chronic malnutrition. Although their clinical benefit is not proved, they carry no significant risk or cost.

Hypocalcemia is common in alcoholic patients with magnesium depletion. The mechanism is related to diminished parathyroid hormone secretion, decreased tissue responsiveness to parathyroid hormone, decreased vitamin D metabolism, and decreased calcium release from bone independent of parathyroid hormone. Correction of magnesium depletion is necessary to restore calcium to normal levels. Hypoalbuminemia, pancreatitis, or vitamin D deficiency also contributes to low serum calcium or low total body stores of calcium in alcoholic patients.[88]

Hypophosphatemia is found in 30 to 50% of hospitalized patients with alcoholism. Phosphorus depletion results from malnutrition, vomiting, respiratory alkalosis, diarrhea, enhanced release of calcitonin, phosphate-binding antacids, and urinary loss (related to vitamin D deficiency and secondary hyperparathyroidism). Hypophosphatemic patients often have low magnesium levels.[89] Rehydration, carbohydrate repletion, and parenteral alimentation further exacerbate phosphorus depletion. Glucose bolus and infusion have been shown to produce a significant fall in serum inorganic phosphate levels. Severe hypophosphatemia (<1 mg/dL) has been associated with acute respiratory failure; myocardial depression; dysfunction of erythrocytes, leukocytes, and platelets; CNS irritability; and rhabdomyolysis.

Although chronic alcoholics requiring admission often have potassium, magnesium, and phosphate depletion, empirical treatment with potassium and phosphate is discouraged. Serum levels and renal function should be determined. Unintended hyperkalemia and hyperphosphatemia can produce significant morbidity, and phosphate infusion exacerbates hypocalcemia if it is present. Because most magnesium is intracellular, a normal serum magnesium level does not rule out decreased total body magnesium stores. If the serum level is normal, total body levels may still be low. As long as renal function is adequate, empirical magnesium treatment can be considered. Abstinence and a proper diet resolve electrolyte and nutritional deficiencies in the ambulatory alcoholic patient who is healthy enough to be treated as an outpatient.

Alcoholic Ketoacidosis

Alcoholic ketoacidosis most frequently occurs in severe chronic alcoholics who have had a recent binge followed 1 to 3 days later by protracted vomiting, decreased food intake, dehydration, and abstinence. Nausea, vomiting, and abdominal pain are common presenting complaints.[90] These patients have tachypnea, dehydration, ketonuria, and little or no glucosuria. Serum glucose levels are usually less than 200 mg/dL. Normal blood pH may be found despite ketonemia because of coexisting respiratory alkalosis and metabolic alkalosis.

The exact mechanism responsible for the increase in ketone bodies is unclear. Acute starvation superimposed on chronic malnutrition as well as release of an alcohol-induced block in ketogenesis allowing marked ketosis may explain the disorder. An increased ratio of reduced (NADH) to unreduced nicotinamide adenine dinucleotide (NAD) in the alcoholic predisposes to the accumulation of β-hydroxybutyrate and the inhibition of gluconeogenesis, which may underlie the common occurrence of hypoglycemia in alcoholic ketoacidosis.

The alcoholic patient with metabolic acidosis presents an interesting dilemma because most of these patients have an

www.ketabpezeshki.com 66485457-66963820

increased anion gap acidosis. Glucosuria may suggest diabetes; crystalluria can be seen in ethylene glycol poisoning; low specific gravity, proteinuria, and casts can be seen in renal failure; leukocytes and bacteria are present with urosepsis; and significant ketones in an otherwise normal urine may indicate starvation or alcoholic ketosis. Elevated levels or a very high osmolal gap (>25 mOsm/kg) is specific (88%) for methanol or ethylene glycol ingestion.[91]

Treatment of alcoholic ketosis consists of normal saline, glucose, thiamine, and correction of hypokalemia. This can be accomplished with 5% dextrose in normal saline and either 30 mEq of potassium chloride or 30 mEq of oral potassium. Bicarbonate is seldom necessary but may be considered in the rare patient with a pH below 7.1. If no serious complicating illness is present, the ketosis is reversed in 12 to 24 hours with this treatment.

Hematologic Effects

The alcoholic presents with myriad hematologic abnormalities. The direct toxic effect of ethanol and its metabolites, secondary nutritional deficiency, and hepatic disease, individually or in combination, affect red blood cells, white blood cells, platelets, hemostasis, and the immune system.[92] Macrocytosis is the most common hematologic manifestation of the chronic alcoholic. It may be caused by folate deficiency, reticulocytosis (the younger reticulocytes are larger), liver disease (producing an abnormal lipid coating of the red blood cell membrane), or vitamin B_{12} deficiency. The most common condition is idiopathic macrocytosis of alcoholism.

Anemia

Several mechanisms cause anemia, which is common in the alcoholic. Megaloblastic anemia resulting from folate deficiency is the most common anemia in alcoholics. The mean corpuscular volume (MCV) is typically increased but may be normal when iron deficiency coexists. Malnutrition, inability of the cirrhotic liver to store folate, excessive urinary loss, and malabsorption decrease folate stores. Alcohol accelerates the development of megaloblastic anemia in individuals with depleted folate (MCV > 100 fL) stores by an unknown mechanism.

Iron deficiency anemia is common and usually a result of blood loss from the gastrointestinal tract. With iron deficiency anemia, the serum iron is decreased, the total serum iron-binding capacity is elevated, and serum ferritin is decreased. Alcoholics frequently have chronic inflammatory diseases, such as endocarditis, tuberculosis, empyema, lung abscess, malignant disease, and hepatic disease. These chronic inflammatory illnesses can produce the anemia of chronic disease, a mild microcytic or normocytic anemia in which the serum iron is low, but in contrast to iron deficiency, the total serum iron-binding capacity is low or low-normal, and serum ferritin is increased.

Ethanol also has a direct toxic effect on erythropoiesis. Bone marrow biopsies reveal vacuolization of erythroid precursors, resulting in decreased reticulocytosis and a reversible sideroblastic anemia. Sideroblastic anemia, usually in the presence of malnutrition with pyridoxine deficiency and folate deficiency, occurs in 25 to 30% of anemic alcoholics.

Leukocyte Abnormalities

Leukopenia is common in the alcoholic patient and has several possible causes. Sepsis, folate deficiency, and hypersplenism all lead to a decreased white blood cell count. Alcohol has a direct toxic effect on white blood cell production in the bone marrow. Granulocyte mobilization (chemotaxis) and adherence are also impaired, resulting in a decreased inflammatory response.

Platelet Disorders

Thrombocytopenia can occur with folate deficiency, sepsis, disseminated intravascular coagulation, or splenic sequestration. The direct toxic effects of alcohol decrease measured survival time and impair production of platelets in the bone marrow, but marrow toxicity will rarely reduce the platelet count below 30,000. Qualitative platelet function is also impaired. Binge drinking is associated with a reactive thrombocytosis potentially responsible for acute stroke and sudden death.[93]

Hemostasis

Alcoholic patients have a bleeding diathesis for many reasons, including thrombocytopenia, qualitative platelet disorders, deficient production of hepatic clotting factors, gastrointestinal variceal formation, and vitamin K deficiency. A complete blood count, peripheral smear, platelet count, reticulocyte count, thrombin time, prothrombin time/INR, and partial thromboplastin time help evaluate episodes of significant bleeding. Bleeding associated with coagulation abnormalities may require fresh frozen plasma for immediate correction of coagulation factor depletion; vitamin K (10 mg IV) takes 6 to 10 hours to reverse the vitamin K–dependent factors II, VII, IX, and X. Because of poor diet and impaired hepatobiliary function, alcoholics may have insufficient vitamin K storage and benefit from vitamin K delivery. However, alcoholic patients with profound liver failure are unable to produce the precoagulation factors II, VII, IX, X, and IV, so vitamin K therapy is futile. Platelet transfusions should be started in the ED for adult patients with active bleeding when the platelet count is less than 50,000/mm^3.

Oncologic Effects

Worldwide, 389,000 annual cases of cancer representing 3.6% of all cancers are alcohol related.[94,95] Although alcohol itself is not carcinogenic, its metabolite, acetaldehyde, is emerging as an important contributor, being able to form stable DNA adducts, to trigger mutations in tumor suppressors and oncogenes, and to interfere with DNA repair. Smoking certainly has an additional role as a cause of neoplasia and is difficult to isolate in these studies.

Chronic alcohol use is associated with an increased incidence of upper alimentary and respiratory tract cancers with a clear dose-response relationship. Specifically, alcohol increases the risk of cancer of the mouth, pharynx, larynx, lung, esophagus, liver, and pancreas.[96] Chronic hepatitis B infection may sensitize the liver to alcohol, producing hepatocellular carcinoma. Women who drink two to five drinks per day have a relative risk of 1.41 for invasive breast cancer compared with nondrinkers.[97] There is also a significant increase in endometrial cancer risk among postmenopausal women who consume more than two alcoholic drinks/day.[98] Moderate alcohol consumption leads to an increased risk of colorectal and prostate cancer.[99]

Hypothermia

Acute alcohol ingestion is one of the most common precipitating factors for accidental hypothermia and occurs in 33 to 73% of patients presenting with a core temperature below 35° C.[100] Alcohol exacerbates hypothermia of other causes with depressed hypothalamic thermoregulation, peripheral vasodilation producing heat loss, CNS depression, sepsis, inability to shiver, hypoglycemia, and increased risk of environmental exposure. Hypothermia may be the presentation of Wernicke's syndrome, possibly caused by lesions of the posterior hypothalamus, hypoglycemia, or sepsis. Intoxicated patients may have slower rewarming rates.

www.ketabpezeshki.com 66485457-66963820

Psychiatric Effects

Forty-five percent of alcohol-dependent adults are diagnosed with one or more additional psychiatric conditions during their lifetime. Of alcoholic men admitted to a psychiatric ward, approximately 40% have another psychiatric disorder unrelated to substance abuse, in particular, antisocial personality disorder, schizophrenia, mood disorders, and anxiety disorders.

Depression and antisocial personality are the two most common psychiatric disorders that correlate with alcoholism, with a prevalence of 30 to 60% in most studies. Chronic alcohol use can produce an imbalance in the serotoninergic system. This imbalance may lead to increased anxiety, aggression, and depression. Interestingly, aggressive behavior is more strongly linked to depression than to alcohol dependence.[101] Secondary depression may be caused by alcoholism, or the primary affective disorder may be present with secondary alcoholism. Mild depressive symptoms are also common in alcohol withdrawal. Antisocial individuals are at high risk for alcoholism and drug dependence, although an unstable, unhappy childhood environment appears to be more important than alcohol to the development of sociopathy. Alcohol increases the lifetime risk of suicide, with 17% of all alcoholics eventually dying by suicide.[102,103] Alcoholism, major depression, and antisocial personality all predispose to suicide, and interaction among the three is particularly dangerous, but the acute risk on any day is difficult to assess.

An alcoholic patient who presents with an apparent psychiatric disorder poses a diagnostic dilemma. Does the patient have a primary affective disorder with secondary alcoholism, or is the patient manifesting anxiety or depressive behavior because of alcoholism? In general, alcoholic patients with psychiatric disorders are best treated with medications that are specific for their psychiatric condition.[104] Many alcoholics with mild depression have spontaneous resolution of symptoms with abstinence. Nevertheless, depression meeting DSM-IV criteria is best treated with antidepressants.[105,106] If abstinence can be achieved, underlying psychiatric disorders are more easily diagnosed and treated.

ALCOHOL-DRUG INTERACTIONS

Alcohol is associated with a vast number of drug interactions (Table 185-6). These may occur through several mechanisms: altered absorption; enhanced metabolism and activated toxic metabolites through the hepatic CYP2E1 pathway; additive or synergistic effects; disulfiram-ethanol–like reactions; and congeners, compounds found in alcoholic beverages. In general, chronic alcoholism is associated with an increased rate of drug clearance as a result of enhanced metabolism and enzyme induction (cytochrome P_{450} system). Conversely, acute alcohol intoxication reduces clearance for other drugs, increasing their serum concentration because of competition for a shared detoxification pathway.[107]

Table 185-6 Effects and Mechanisms of Alcohol-Drug Interactions

CLINICAL EFFECT	MECHANISM	DRUGS INVOLVED	COMMENTS
Increased blood alcohol levels	Inhibition of gastric ADH	Cimetidine Ranitidine Aspirin	Debatable role
Increased blood alcohol levels	Increased rate of gastric emptying	Cisapride Erythromycin	
Liver damage	Increased hepatotoxicity (chronic or "heavy" alcohol use) Decreased metabolism of drug (acute alcohol use)	Acetaminophen Isoniazid Phenylbutazone Narcotics Barbiturates Benzodiazepines Warfarin	"Heavy" drinkers can experience severe consequences even with therapeutic doses. "Binge" drinkers may have toxicity from standard doses.
May require higher dosages	Induction of enzymes	Benzodiazepines Phenytoin Propranolol Warfarin	Chronic alcoholics
Increased bleeding time		Aspirin NSAIDs	
Sedation		Antihistamines	
Psychomotor impairment	Disulfiram-like reactions	Barbiturates Benzodiazepines Narcotics Tricyclic antidepressants Oral hypoglycemics Antibiotics: metronidazole, sulfonamides, griseofulvin, cefoperazone Nitroglycerin	
Hypoglycemia		Long-acting oral hypoglycemics	
Hypotension		Aldomet Hydralazine Nitroglycerin

Enhanced Metabolism and Toxic Metabolites

Most alcohol is metabolized by ADH. A small percentage of alcohol is metabolized by the MEOS–cytochrome P_{450} system, which is also responsible for the metabolism of many drugs. The MEOS metabolic pathway is enhanced in chronic alcoholics, which is associated with the acceleration of the degradation of these other drugs. For example, the half-lives of warfarin, phenytoin, and isoniazid are 50% shorter in abstaining alcoholics than in nondrinkers. Barbiturates, diazepam, propranolol, and rifampin may have increased rates of clearance and shorter half-lives when they are taken by chronic alcoholics. This effect can persist for days to weeks after the cessation of drinking.[58,108]

Acetaminophen is the most widely used analgesic in the United States and is often recommended to alcoholic patients instead of NSAIDs to prevent gastritis. Chronic alcohol ingestion may enhance acetaminophen hepatotoxicity by accelerating the biotransformation to a toxic metabolite on the basis of a few case reports of severe or lethal acetaminophen toxicity in alcoholics taking therapeutic doses. Increased vulnerability seems to occur immediately after cessation of drinking. A synergistic effect apparently occurs with alcohol, fasting, and acetaminophen use in combination with depleted glutathione stores. A prospective observational study suggested that acute ethanol intake may be associated with a lower risk of hepatotoxicity after acetaminophen overdose.[109] Greatly elevated AST levels (3000-48,000 in one series), increased ALT levels, and greatly elevated prothrombin/INR times help distinguish acetaminophen hepatotoxicity from alcoholic hepatitis.[107]

Additive or Synergistic Effects

Alcohol has long been known to have additive or even synergistic effects with several drugs. Acute intoxication decreases the rate of drug metabolism, which is at least partially explained by competition for the same enzymatic process in the liver. For example, ethanol has additive sedative effects when it is taken with first-generation antihistamines, barbiturates, cyclic antidepressants, benzodiazepines, phenothiazines, propoxyphene, propofol, and narcotics. Alcohol may also increase the activity of methyldopa and nitroglycerin. Alcohol can increase tetracycline levels by 30%. Selective serotonin reuptake inhibitors do not appear to affect alcohol kinetics or psychomotor performance.

When cocaine and ethanol are taken concomitantly, the unique metabolite, cocaethylene, is a neurologically active compound that is significantly more toxic than cocaine to the heart, liver, and brain and more addicting and more lethal than cocaine alone. Cocaethylene produces a higher incidence of confusion, lower mean Glasgow Coma Scale (GCS) scores, and a higher incidence of violent trauma and more often requires endotracheal intubation.[110] Hemodynamically, these patients demonstrate an elevated heart rate (1.5-5 times normal) and blood pressure higher than with either drug alone. Sudden death is increased 18- to 25-fold above that associated with use of cocaine alone. Plasma levels of cocaine in this combined group were higher than in those who used cocaine alone.[111]

Ethanol increases aspirin-induced prolongation of bleeding time and reduces the metabolism of warfarin, leading to increased anticoagulant effects. There is an increased risk of upper gastrointestinal bleeding when alcohol is combined with NSAIDs. This may be the most dangerous additive or synergistic effect of alcohol.[112]

Disulfiram and Similar Reactions

Most patients pretreated with disulfiram (Antabuse) who then consume even small amounts of alcohol experience an extremely unpleasant reaction. These patients have a hypersensitivity to ethanol and experience a direct response within 15 minutes and lasting 30 minutes to several hours. The reaction consists of skin flushing on the head that spreads to the trunk along with nausea, vomiting, headache, chest and abdominal discomfort, diaphoresis, vertigo, palpitations, and confusion. A severe reaction may produce hypotension, seizures, and dysrhythmias. Disulfiram-ethanol reaction is thought to occur by the accumulation of acetaldehyde secondary to inhibition of the aldehyde dehydrogenase enzyme, which may be deficient in many Asians, or another unknown toxic factor. This incapacitating reaction has been used to discourage chronic alcohol ingestion.

A similar but milder disulfiram-ethanol–like reaction has been described when alcohol combines with several different drugs. The reaction may occur days to weeks after the last dose of medication. Four cephalosporins (cefamandole, cefoperazone, cefotetan, moxalactam), metronidazole, chloramphenicol, griseofulvin, nitrofurantoin, sulfonamides, all sulfonylureas, and chloral hydrate have produced this reaction in combination with alcohol. Life-threatening toxic reactions between griseofulvin and small amounts of alcohol have been reported.[113] Treatment for disulfiram reaction is usually just observation, an antiemetic for symptoms and intravenous fluids, and rarely dopamine for severe hypotension.

Oral Hypoglycemics

Profound hypoglycemia can occur when alcohol and oral hypoglycemic agents are combined. Patients taking metformin may have an increased risk for development of lactic acidosis when it is combined with heavy drinking. A disulfiram-ethanol–like reaction has been described with many hypoglycemic agents.[108]

ADOLESCENT PATIENT

Although a significant percentage of children drink alcohol, there are as yet few established screening instruments for this population. The usual age at first drinking, independently of the family, is about 15 years (although this varies across cultural groups) and has not changed much in decades.[6] The period of heaviest drinking is usually between 18 and 22 years of age and also does not differ between those with future alcohol-use disorders and the general population. More than 60% of teenagers, even those without alcohol-use disorders, have experienced drunkenness by the age of 18 years, and about 30% have given up events such as school or work to drink or have driven while intoxicated.

Alcohol is often associated with the three leading causes of death among youth: unintentional injury, homicide, and suicide.[114] Adolescent drinking is associated with many negative consequences including suicide, carrying weapons, driving under the influence and resultant fatalities, unsafe or increased sexual activity, sexual assault, and date rape. Seventy-eight percent of high school students have tried alcohol, and 30% admit to binge drinking at least once a month.[115] Binge drinking, typically defined as drinking more than five drinks on an occasion, accounts for 90% of the alcohol consumed by 12- to 17-year-old youths.[114]

The age at drinking onset may be an indicator for increased risk of alcohol-related injury. Adolescents who began drinking regularly before the age of 14 years are at least three times more likely to be diagnosed with alcohol dependence than are those who began drinking at the age of 21 years. In addition, adolescents who began drinking before the age of 21 years were significantly more likely, during their lives, to be injured while under the influence of alcohol.[116]

www.ketabpezeshki.com 66485457-66963820

ELDERLY PATIENT

Unhealthy drinking is found in up to 15% of elderly (older than 65 years) ED patients.[117] Fifty percent of older people drink alcohol, and 2 to 4% meet criteria for alcohol abuse or dependence. Common screening tests (e.g., CAGE) tend to be less sensitive in this age group. Alcohol may exacerbate underlying disease by masking anginal chest pain, worsening hypertension, and inducing dysrhythmias.[118] However, elderly persons consuming low to moderate levels of alcohol may have a decreased risk for development of dementia and heart failure.[119] More than 90% of people aged 65 years or older use more than one prescribed medication.[120] Aging alters gastrointestinal absorption, lowers volume of distribution, diminishes homeostatic responses, and reduces renal and hepatic function.[108] Elderly persons also demonstrate increased end-organ sensitivity, particularly involving the CNS, with concomitant drug use increasing their risk for alcohol and drug interactions.

A protective effect on cognitive functioning has been shown with moderate alcohol consumption, particularly in women.[121] Moderate consumption is associated with a 38% reduced risk of dementia.[122] Still, elderly patients are more likely to have neuropsychiatric complications of alcoholism: sleep problems, anxiety, depression, and dementia. Alcohol is involved in one third of suicides in elderly persons. Older subjects also perform less well than younger subjects on tests of perception and attention at all blood alcohol levels. This may result in an increased risk of fractures from falling and osteoporosis. However, recent evidence suggests that compared with abstinence, consumption of up to one drink per day is associated with a decreased risk of osteoporotic hip fracture and a beneficial effect of moderate alcohol consumption on bone density.[123]

PREGNANCY

Many scientific reports confirm alcohol's teratogenic effects. According to the National Institute on Drug Abuse, almost 19% of all children born in the United States have been exposed to alcohol during gestation.[124] Pregnant women who report use of any alcohol, binge drinking, or frequent drinking are more likely to be older than 30 years, employed, and unmarried.[125]

Fetal alcohol syndrome is characterized by a triad of CNS defects, including mild to moderate mental retardation; dysmorphology, involving mostly facial structures; and growth deficiencies, usually consisting of short stature and microcephaly.[126] Fetal alcohol syndrome is now considered the most common identifiable source of mental retardation. Children exposed to prenatal alcohol exhibit increased activity levels, cognitive and attention deficits, perseverative behavior, and language and motor problems, which persist into adulthood.[127]

Ethanol rapidly diffuses across the placenta and is distributed to all fetal tissue with a predilection for gray matter. Although infants of mothers who drink heavily have the poorest outcome, children of mothers who consume only two or three alcoholic drinks a day also display abnormalities. Even in the absence of growth retardation or congenital abnormalities, children born to women who consume excessive alcohol during pregnancy appear to be at increased risk for attention deficit disorders. These findings are referred to as fetal alcohol effects.

Whereas there is no known safe amount of consumption during pregnancy, in a cohort study of more than 5000 patients observed for 14 years, an average of less than one drink per day in early or late pregnancy showed no measurable impact on a child's learning or cognitive functioning. Adverse outcomes in this study were associated with an average of more than one drink per day, binge drinking, and consumption of alcohol later in pregnancy.[128] The American Academy of Pediatrics recommends abstinence from alcohol for women who are pregnant or who are planning a pregnancy.[129]

TRAUMA

The single greatest contributor to alcohol-related mortality in the United States is unintentional injury, accounting for approximately 26,000 deaths per year.[130] The importance of alcohol misuse as a precursor to serious injury is widely accepted enough that since 2006 the American College of Surgeons Committee on Trauma requires screening for problem drinking for designation as a level I or level II trauma center. In addition, level I trauma centers must provide an intervention for problem drinkers identified. Alcohol and trauma are inextricably linked. Independently, the tragic effects of each are numerous; in combination, they are staggering. Injury is the leading cause of death between the ages of 1 and 44 years, accounting for more than 50 million injuries per year. In the United States, alcohol is the major risk factor for virtually all categories of intentional and unintentional injury. Besides increasing the frequency and severity of injury, alcohol significantly complicates the management of the trauma victim.[131] Alcohol intoxication often complicates the initial assessment of injury severity, resulting in an increased need for invasive diagnostic and therapeutic procedures (e.g., intubation, CT scan, intracranial pressure monitoring).[132]

Alcohol may diminish the patient's capacity to respond to hemorrhagic shock by altering hemodynamic effects and acid-base balance. Volume depletion as a result of the diuretic effect of alcohol or vomiting can impair the reserve of the intoxicated trauma patient. Peripheral vasodilation caused by alcohol may contribute to hypotension and hypothermia. Although these effects may be minimal, they underscore the need for early and adequate fluid resuscitation in these patients. Intoxicated patients with severe non-neurologic trauma may have lower blood pressures and carbon dioxide levels (indicative of a compensatory hyperventilation) on hospital arrival compared with sober patients. More important, a poorly understood cardiac depressant effect also increases the depth of shock and volume requirements for resuscitation. Alcohol-induced skin vasodilation may be accompanied by an increase in skeletal muscle, mesenteric, and renal bed constriction and left ventricular stroke work. Thus the overall effect on systemic vascular resistance and blood pressure may be balanced.[133]

Intoxication renders the signs and symptoms of intra-abdominal and retroperitoneal injury less reliable than usual. If the risk of an intra-abdominal injury exists, further evaluation (e.g., ultrasonography, CT) should be considered.

Alcohol intoxication predisposes to abdominal wall laxity and thus less protection from blunt trauma.[133] These patients are also likely to have full stomachs, increasing the risk of gastric injury after trauma and predisposing to vomiting and aspiration, especially during airway management. The fatty liver changes of alcoholism can result in hepatomegaly. Portal hypertension in alcoholics may produce splenomegaly. These organs can become more vulnerable to the effects of trauma because of their enlarged size, protrusion beneath the protection of the ribs, and increased intracapsular pressure.

Alcohol intoxication contributes to CNS injury in many ways. It is associated with aggressive behavior, impaired reflexes and coordination, and inappropriate avoidance responses. A higher degree of trauma to the spinal cord and much worse neurologic and functional recovery occur in patients who are intoxicated during trauma compared with sober patients.[134]

www.ketabpezeshki.com 66485457-66963820

Experimental evidence suggests that alcohol acts synergistically with mechanical injury of the spinal cord to amplify the trauma response by increasing edema formation within the contused tissue.[135]

No consensus exists on the indications for an emergency CT scan in patients with “minor head injury” (loss of consciousness, post-traumatic amnesia, GCS score of 14 to 15, normal findings on neurologic examination). One disturbing prospective study found that the GCS score and 1 hour of observation were unable to predict abnormal head CT scans in intoxicated patients with minor head trauma. Patients with signs of head trauma and focal or generalized seizures need an urgent CT scan. CT scans of the head should be performed for any patient with deteriorating mental status, focal neurologic findings, new-onset seizures even without obvious signs of history of trauma, failure to improve over time, or mental status changes out of proportion to the degree of intoxication.[136]

The good news is that during the past 20 years, there has been a decline in the number of alcohol-related fatalities. Five states (Hawaii, Illinois, Indiana, Pennsylvania, and Utah) have enacted mandatory hospital and provider reporting laws.[137]

ADMISSION GUIDELINES AND DISPOSITION

Most alcoholics suffer from a combination of medical, psychiatric, and social problems. Hospitalization is often necessary to diagnose and to treat these multiple problems. Moreover, with alcoholics who are no longer able to care for themselves, hospitalization is often dictated for this reason alone. Unfortunately, many managed care and Medicaid plans limit or do not cover inpatient detoxification. In choosing medical versus psychiatric admission, a medical illness usually takes priority. Optimal outpatient therapy for chronic alcoholics includes concerned family or friends to ensure that the patients take their medications properly, keep follow-up appointments, abstain from alcohol, and maintain an adequate diet. Alcoholic patients who undergo outpatient treatment need close supervision; therefore, a follow-up clinic appointment within 24 to 48 hours should be considered.

Acute Intoxication

Acute intoxication alone seldom requires admission. However, combined alcohol-drug overdose or associated medical, psychiatric, or social problems may require hospitalization. Acute alcohol intoxication is a diagnosis of exclusion reached after adequate observation to ensure that the altered mental status resolves.

Alcohol levels that may be tolerated by an adult can be lethal in children. It is prudent to admit children with acute intoxication unless close psychosocial follow-up can be ensured. Children presenting with hypoglycemia or medical complications should be admitted. Child abuse or neglect should be considered.

Alcohol Withdrawal

Patients with signs of major withdrawal (fever, hallucinations, confusion, extreme agitation) require admission. Patients with mild alcohol withdrawal can be observed in the ED. After 4 to 6 hours of observation and treatment, the alert, oriented patient whose vital signs, physical examination findings, and results of appropriate laboratory analysis are within normal limits may be released with appropriate medications and aftercare instructions. Nevertheless, the patient requires treatment for the underlying disease of alcoholism and should be advised or referred accordingly.

Seizures

Patients experiencing their first alcohol-related seizure may be admitted. Admission allows initiation of drug therapy, diagnostic evaluation, and continued monitoring of the patient’s status. However, the alcoholic patient with a first-time alcohol-related seizure may be discharged to a suitable social situation when the patient’s alcohol withdrawal is mild and controlled either by supportive care or with low-dose benzodiazepines; the diagnostic workup, including a head CT scan, is unremarkable; the patient has had fewer than two seizures; and the patient has been observed to be alert and oriented, with normal vital signs, physical examination findings, and laboratory study results, during the 6 hours since the last seizure, and appropriate outpatient follow-up can be ensured.

Patients with a documented history of alcohol-related seizure can be discharged if they have had no more than two alcohol-related seizures during a 6-hour period with a lucid interval between seizures and are observed to be seizure free and at baseline mental and physical status for at least 6 hours after their last alcohol-related seizure. Three to five brief, self-limited seizures may occur with alcohol withdrawal seizure. Nevertheless, admission for patients with two or more seizures is advised because of the potential for deterioration to status epilepticus. This is especially appropriate in the malnourished, immunocompromised, homeless, or noncompliant alcoholic patient.

Patients with partial seizures or focal neurologic findings on physical examination require admission unless these findings are previously documented. Patients with seizures associated with head trauma or with mixed alcohol-drug withdrawal are admitted. Status epilepticus or recurrent seizures during ED observation indicate a lack of seizure control also requiring hospitalization.

Psychiatric and Social Problems

Alcoholic patients requiring admission with acute intoxication, alcohol-related seizure, alcohol withdrawal, or medical or surgical disorders are usually best managed in acute care units rather than by a general psychiatric service. Some psychiatric and social conditions in the alcoholic can be better handled on a general psychiatric unit: psychosis, exacerbation of schizophrenia, depression with suicidal tendencies, any patient who is a danger to self or others, or alcoholic hallucinosis with an otherwise clear sensorium.

Patients who are no longer able to care for themselves may also require admission. Although these patients’ ultimate destination is a rehabilitation center or a board-and-care program, hospitalization may be necessary to rule out medical or psychiatric illness and to treat impending withdrawal symptoms. Patients who wish to stop drinking are usually admitted to a detoxification unit for treatment of impending withdrawal. Data and interest are increasing for outpatient drug therapy in alcohol dependence. The U.S. Food and Drug Administration has approved disulfiram, naltrexone, acamprosate, and topiramate for treatment of alcohol dependence.[104] There is growing evidence that patients with alcohol dependence who carry a particular variant of an opioid receptor gene are more likely to respond to naltrexone, raising the possibility that genetic tests may one day guide medication selection.[138] Naltrexone, ondansetron, acamprosate, and acamprosate plus naltrexone have had mixed results facilitating abstinence.[139,140] The role of medications in combination with behavioral therapy is actively investigated.[141,142]

Several other medications are under active study and are sometimes prescribed for alcoholism treatment on an unapproved or off-label basis. Baclofen, because of its anticraving action and

www.ketabpezeshki.com 66485457-66963820

safety, could have an important role for treatment of alcohol-dependent patients with advanced liver disease.[143] Gabapentin is used as monotherapy or as an add-on pharmacotherapy in outpatient settings in the control of alcohol consumption and craving and in helping patients achieve abstinence.[144] Ondansetron may show benefit in early-onset but not in late-onset alcoholics.[145]

Brief intervention has reduced alcohol consumption in some well-designed ED studies but not in others.[146,147] Alcohol dependence and a positive screen for alcohol-related injuries are decreased after screening and brief intervention.[148] Internet-based interventions show promise for reducing alcohol consumption, especially among those meeting criteria for hazardous or harmful drinking.[149] Telephone contact after the ED visit may be another effective tool to screen injured patients for hazardous drinking and to offer brief intervention while avoiding interruptions to patient flow.[150] Referral and brief intervention are warranted.[151] Most communities have either an Alcoholics Anonymous (AA) chapter or a treatment center for anyone who desires help with alcohol. In smaller communities, clergy or social workers can usually arrange rehabilitation.

Alcohol kills—it kills the alcoholic and it kills unintended victims by the acts of inebriated persons. Whereas medical, psychological, or social problems bring the alcoholic to the ED, the underlying problem is alcoholism and the ultimate goal is abstinence. This disease surely progresses if alcoholism is not first recognized and the patient is never given the opportunity to participate in a rehabilitation program.[152] The emergency physician can intervene on behalf of the patient and the public.

KEY CONCEPTS

- Moderate alcohol consumption is defined as one or two drinks per day for men and one drink for women.
- Benzodiazepines are the main treatment of alcohol withdrawal and alcohol withdrawal seizures.
- Inappropriate alcohol consumption or alcohol dependence should be considered in patients in almost any clinical situation, including trauma, potential drug-alcohol reactions, pneumonia, cardiomyopathy, new-onset atrial fibrillation, hepatitis, gastrointestinal bleeding, pancreatitis, altered mental status, depression, suicide, magnesium deficiency, and anemia.
- Minor alcohol withdrawal occurs as early as 6 hours and usually peaks at 24 to 36 hours after the cessation of or significant decrease in alcohol intake.
- Major alcohol withdrawal occurs after 24 hours and usually peaks at 50 hours (but occasionally takes up to 5 days) after the decrease or termination of drinking.
- Delirium tremens is the extreme end of the alcohol withdrawal spectrum and consists of gross tremor, profound confusion, fever, incontinence, and frightening visual hallucinations.
- Not all alcohol-related seizures are alcohol withdrawal seizures.
- Brief intervention in the emergency department can decrease drinking and its long-term consequences

Chapter 186

Substance Abuse

Alicia B. Minns and Richard F. Clark

PERSPECTIVE

The use and abuse of psychoactive substances are not unique to our country or century. People used hallucinogenic plants to achieve altered states of consciousness in prehistoric times, and psychoactive substances have been used in all eras and cultures. As Osler remarked, "The desire to take medicine is, perhaps, the great feature which distinguishes man from other animals."[1] The human cost of substance abuse is high, and deaths secondary to the use of psychoactive substances are common. In the United States, illicit drug use results in thousands of deaths each year (Box 186-1).[2]

A major barrier to appropriate recognition and treatment of substance abuse is the lack of a precise definition. The American Psychiatric Association defines it as a maladaptive pattern of drug use associated with some manifest harm to the user or others.[3] Physicians have a difficult time recognizing such abuse when up to 44% of emergency department (ED) patients report underlying chronic pain syndromes.[4] Chronic pain may not manifest the typical overt sympathetic changes or physical findings of acute pain.[5] Therefore, emergency physicians constantly walk a tightrope between undertreating legitimate pain and inappropriately rewarding substance abusers with controlled medications.

EPIDEMIOLOGY

A variety of stereotypes come to mind in compiling the profile of a substance abuser. These stereotypes pose dangerous traps for the clinician. Physicians are likely to ignore the possibility of drug intoxication in the well-dressed businessman or in those at the extremes of age. Yet children may ingest psychoactive substances they find in homes where drugs are used.

Abuse of prescription and over-the-counter (OTC) drugs by adolescents is on the rise. According to the 2005 Partnership for a Drug-Free America's 18th annual self-administered study of 7300 teenagers in grades 7 to 12, one in five (19%, or 4.5 million) report abusing prescription medications and one in ten (10%, or 2.4 million) report abusing cough medications to "get high." This use is on par with or higher than the abuse of illegal drugs such as ecstasy and cocaine.[6] Dextromethorphan abuse has become epidemic in the last decade. Increasing numbers of teens are ingesting dextromethorphan-containing OTC products such as Coricidin HBP Cough & Cold tablets,[7] known on the streets as triple C, red devils, red C, red box, or skittles. Other dextromethorphan compounds include cough medicines, such as NyQuil and Robitussin DM, that provide the sought-after high known as the robo-buzz. Adolescents may also abuse medication used to treat obsessive-compulsive disorder and attention-deficit/hyperactivity disorder. Methylphenidate and related compounds have been a particular concern. Tablets can be abused orally, or they can be crushed and the powder injected or snorted. Despite its abuse potential, experts disagree about the extent to which methylphenidate is diverted from therapeutic use to abuse in preteens and adolescents.[8] In addition, some parents deliberately give psychoactive substances to their children to calm or to abuse them.

The emergence of "legal highs" has become a concerning trend. Numerous synthetic and naturally derived psychoactive substances are easy to obtain from Internet websites, "head shops," and local suppliers. One such example is known as bath salts. These products are available in small quantities, with packaging that usually includes the disclaimer "not for consumption" to avoid regulation.[9] Bath salts contain synthetic cathinones, which are pharmacologically similar to methamphetamine and MDMA (ecstasy) and produce similar clinical effects.[10] A variety of adverse effects have been reported from cathinone derivatives, including tachycardia, hypertension, agitation, hyponatremia, hallucinations, paranoia, and suicide.[9-11] The legal status of bath salts is rapidly changing. The U.S. Department of Justice Drug Enforcement Administration has temporarily placed three of the synthetic stimulants under Schedule I of the Controlled Substances Act; however, numerous other synthetic cathinones have been found in these products.[9]

The elderly also abuse substances, and geriatric patients may suffer new-onset psychosis as a result of sympathomimetic abuse or drug withdrawal. Drug use is frequent among pregnant women, resulting in both maternal and fetal morbidity. A study of an inner-city population reported that 19% of women had a positive urine toxicology screen for at least one of seven substances at the time of admission for delivery.[12] Manifestations of abuse may be acute, as in abruptio placentae or premature birth, or insidious, producing growth restriction and birth defects. Drug problems are more prevalent among the disadvantaged minority and lower socioeconomic groups. As a result, these groups are disproportionately affected by drug-related problems, such as incarceration, acquired immunodeficiency syndrome, and tuberculosis.

The Drug Alert Warning Network (DAWN) collects data from hospital EDs and medical examiners that include drug-related visits or deaths. The data consist of patients who abuse illegal drugs or use legal substances for a nonmedical purpose. According to DAWN, the drugs of misuse or abuse most commonly involved in deaths are cocaine, opioids, antidepressants, benzodiazepines, stimulants, and club drugs.[13]

For 2005, DAWN estimated that 816,696 ED visits involved an illicit drug; cocaine was involved in 448,481, marijuana in 242,200, heroin in 164,572, and stimulants (including amphetamines and methamphetamine) in 138,950 ED visits. Other illicit drugs (phencyclidine [PCP], ecstasy, and γ-hydroxybutyric acid [GHB]) were much less frequent.[14] Despite efforts to control nonmedical

use of prescription drugs in the United States, the estimated number of ED visits for nonmedical use of opioid analgesics increased 111% during 2004-2008 (from 144,600 to 305,900 visits) and increased 29% during 2007-2008. The highest numbers of these ED visits were recorded for oxycodone, hydrocodone, and methadone, all of which showed statistically significant increases during the 5-year period. The estimated number of ED visits involving nonmedical use of benzodiazepines increased 89% during 2004-2008 (from 143,500 to 271,700 visits) and 24% during 2007-2008. In 2008, the number of ED visits involving nonmedical use of prescription or OTC drugs matched the number of ED visits involving illicit drugs.[15]

Illicit drug use generates significant costs to the health care system. In 2001, the hospital and ambulatory care costs of illicit drug use as a whole were an estimated $1.34 billion. The cost for illicit drug–related skin and soft tissue infections alone was estimated to be more than $193 million.[16] More recently in 2008, the cost of hospital days stemming from drug overdoses without alcohol involvement was estimated to be $737 million.[17]

PHARMACOLOGY

Knowledge of drug interactions assists in the diagnosis and care of substance abuse victims. A careful medication history for all legal and illegal drugs, including ethanol, may pinpoint the source of an adverse reaction. For example, a variety of agents can increase the effects of cocaine. The coingestion of ethanol and cocaine results in an active metabolite, cocaethylene, that also enhances and magnifies cocaine's effects. Serotonin syndrome, manifested by muscle rigidity, hyperthermia, diarrhea, and seizures, may result when sympathomimetic drugs are taken concurrently with selective serotonin reuptake inhibitors such as fluoxetine. Amphetamines elevate serotonin either directly or by reversible inhibition of monoamine oxidase. In fact, a selective serotonin reuptake inhibitor can result in flashbacks in prior amphetamine

Figure 186-1. Freon abuser. (Copyright Stephen A. Colucciello.)

users. Monoamine oxidase inhibitors can provoke hypertensive crisis in patients taking sympathomimetics. Interactions between medications commonly prescribed for patients with human immunodeficiency virus (HIV) infection and recreational drugs may be associated with serious clinical consequences because protease inhibitors and non-nucleoside reverse transcriptase inhibitors (NNRTIs) can inhibit or induce the cytochrome P_{450} system, which could result in either drug accumulation or toxicity or withdrawal reactions.[18] For example, patients maintained with methadone who are subsequently treated with NNRTIs are at risk for development of methadone withdrawal by NNRTI-mediated enzyme induction.[18]

Household products and medications also have abuse potential. For example, dextromethorphan in common cough medications is converted into a substance (dextrorphan) similar to ketamine and PCP, which causes dissociative effects by antagonizing the *N*-methyl-D-aspartate (NMDA) receptor. Recreational users describe mild hallucinations and an "out-of-body" state.[19] Some common chemicals in the home and workplace have an intoxicating effect that may be unexpected. Solvents, paint, lacquers, glues, aerosols, refrigerants, and other propellants (Fig. 186-1) are readily accessible for abuse among children and teens. Inhaled hydrocarbons, such as toluene, are rapidly absorbed and easily pass through the lipophilic blood-brain barrier to give an inexpensive high.

Illicit drug laboratories have poor quality control, and many drugs are combined or "cut" with other substances to increase profits. Up to 50% of street samples lack the alleged drug. Some additives, such as local anesthetics or sugars, may be innocuous, but others, such as strychnine, may be lethal. Levamisole, a widely available anthelmintic agent, is now a common cocaine adulterant and can result in life-threatening agranulocytosis, leukoencephalopathy, and cutaneous vasculitides.[20] Other drugs, such as PCP, are misleadingly sold as a different drug, such as lysergic acid diethylamide (LSD). During the 1990s, many doses of purported ecstasy (MDMA) actually contained amphetamine drug mixtures or even simple caffeine or ephedrine.[21,22] Drug combinations and unanticipated additives or substitutions may produce a clinical picture discordant with what the patient claims to have taken.

"Look-alike" drugs may also have toxic effects. Teens in particular may take look-alike or "knock-off" drugs that look like a desired product, such as Ritalin or Coricidin, in the hope of getting high, when in reality they may suffer unanticipated effects from an unrelated medication sold by an unscrupulous dealer. Teenagers can present with dystonias after unsuspectingly taking haloperidol instead of diazepam (each can have a "letter" inscribed in the middle of the pill).

CLINICAL FINDINGS

History

A drug history should be obtained from patients reporting drug reactions, acute anxiety or other psychiatric problems, and acute cardiopulmonary or neurologic symptoms. This information should include use of legal and illegal substances, prescription and OTC medications, vitamins, herbals, tonics, and potions. When it is appropriate, the physician should specifically ask if the patient is suicidal. A physician who is neutral and nonjudgmental in approach is more likely to obtain accurate information.

Parents should be asked what they believe their son or daughter took and when. The "street name" may be unfamiliar to the emergency physician; there are numerous websites available for reference information, such as www.whitehousedrugpolicy.gov/pdf/street_terms.pdf.[23] Regardless, there is no guarantee that the purported ingestant is pure or unadulterated; therefore, a careful examination may provide the most reliable clues about the exposure. Prehospital personnel, family members, and friends may be able to offer additional information. Patients who are brought from the scene of a club, "rave," or circuit party with altered mental status may be under the influence of a club drug such as MDMA (ecstasy), GHB, flunitrazepam (Rohypnol), or ketamine. Other club drugs, such as Verve and Jolt, contain γ-butyrolactone (GBL) and are sold on the Internet as precursor molecules to GHB. These dangerous drugs are especially appealing to teens.[24]

The RAFFT questionnaire may be useful in detection of substance abuse in adolescents. Each yes response receives a score of 1, and each no response receives a score of 0. The scores for the five questions are added together, and a RAFFT total score of 3 or more indicates that an individual needs further assessment[25]:

Relax: Do you drink/use drugs to relax, feel better about yourself, or fit in?
Alone: Do you ever drink/use drugs while you are by yourself, alone?
Friends: Do any of your closest friends drink/use drugs?
Family: Does a close family member have a problem with alcohol or drugs?
Trouble: Have you ever gotten into trouble from drinking or using drugs?

Injection drug abusers often have infectious complications, such as septic pulmonary emboli, skin or brain abscesses, endocarditis, and HIV-related disease. Wound botulism can also be a complication of injection drug use.

Physical Examination

Documentation of vital signs is essential. Temperatures are frequently neglected in violent or agitated patients, and external skin temperature can be misleading. Because rapid mouth breathing, dry mucous membranes, and agitation may produce unreliable oral temperatures, a rectal temperature can confirm suspected alterations in temperature. Patients should be undressed and completely examined, with particular attention paid to the skin, pupils, and mental status, and evaluated for signs of trauma. Needle marks and track marks may be found in unusual areas, such as the supraclavicular space.

Physical examination includes evaluation for specific toxic syndromes. The presence of diaphoresis, mydriasis, tachycardia, hypertension, abnormal mental status, and urinary retention suggests sympathomimetic toxicity. In comparison, the anticholinergic (antimuscarinic) syndrome has these same features with the exception of dry skin and mouth Also, patients with antimuscarinic delirium tend to be less violent and paranoid than those with sympathomimetic toxicity. The mental status evaluation should address both the level of consciousness and appropriateness of affect. Specific physical findings, such as dental disease, skin abscesses, cardiac murmur, or focal neurologic abnormalities such as tremor or ataxia, can assist in identification of chronic drug abuse. Dental disease, with extensive caries, has traditionally been attributed to methamphetamine use, but it is common with other forms of chemical dependency.[26] The skin provides important clues to substance abuse, such as residue of chemicals or drugs on the hand or face or track marks from injection drug use.

DIFFERENTIAL DIAGNOSIS

It is unreliable to assume that abnormal behavior or altered mental status in the unkempt young patient is due to drug intoxication. Many serious illnesses can be manifested as an overdose, including sepsis, meningitis, encephalitis, head trauma, unintentional poisoning (e.g., carbon monoxide), hypothermia, heatstroke, intracranial hemorrhage, complex seizures, and drug withdrawal. Hypoglycemia and other metabolic and endocrine derangements are important considerations. Similarly, drug intoxication should be considered in the differential diagnosis of altered mental status or abnormal vital signs regardless of age. Although patients with decompensated psychiatric disease can present similarly to those with drug intoxication, the hallucinations from psychiatric disease are usually auditory in nature, whereas hallucinations from drug intoxication or withdrawal tend to be visual hallucinations. Otherwise, the behavior and agitation associated with drug abuse can be similar to those of decompensated psychiatric disease.

COMPLICATIONS

Illicit drugs produce a wide variety of complications involving all major organ systems. Neurologic complications are especially prominent. Up to 10% of strokes are secondary to drug abuse.[27] Cerebral infarction, cerebral and cerebellar hemorrhage, and subarachnoid bleeding are often secondary to use of cocaine and amphetamines and, occasionally, PCP or heroin.[28] Single generalized tonic-clonic seizures are common with substance abuse, and status epilepticus can occur. Although sympathomimetics such as cocaine and amphetamines are responsible for the majority of seizures, heroin, tricyclic antidepressants, and PCP are high risk. Withdrawal from benzodiazepines and alcohol can also result in seizures, including status epilepticus.

The dangers of substance abuse extend far beyond the toxic effects of a particular drug. Associated hazards include HIV infection, not only secondary to injection but also from the promiscuous lifestyle associated with the drug culture. The prevalence of HIV infection in injection drug users is approximately 12 to 17%.[29]

Recent declines in the incidence of HIV infection among injection drug abusers are encouraging, but resurgences have been associated with needle sharing and inadequate methadone treatment.[30] Accompanying this phenomenon is a decrease in hepatitis B and hepatitis C among injection drug users in some U.S. cities. This is probably due to increases in preventive measures, such as needle-exchange programs, condom use, and vaccination for hepatitis B.[31] Almost 20% of cocaine abusers have a positive tuberculosis skin test result. Sexually transmitted disease is common, especially in the sex-for-drugs culture of crack cocaine. Syphilis, in particular, is endemic among crack abusers.

The lungs are target organs for impurities in intravenous drugs, and pyrogens become trapped in this massive filter. This can produce "cotton fever," characterized by high fever, tachycardia, and tachypnea 10 to 20 minutes after injection.[32] This self-limited illness contrasts with the long-term restrictive and obstructive lung diseases with the prolonged intravenous abuse of methylphenidate. Right-sided endocarditis is a frequent sequela of chronic injection drug abuse, and the nonspecific influenza-like symptoms that accompany this disease can mislead the clinician. In addition

www.ketabpezeshki.com 66485457-66963820

to endocarditis and HIV infection, injection drug abusers have septic pulmonary emboli, cellulitis, botulism, tetanus, and other infectious complications. They may have unusual sites of osteomyelitis or septic arthritis involving the spine or sternoclavicular or sacroiliac joints.

Psychiatric complications of substance abuse are frequent and include anxiety, depression, suicidal ideation, mood swings, paranoia, and panic attacks. Paranoia and depression and associated suicide attempts are common among stimulant abusers, and hallucinations of parasites under the skin (formication) are frequent in those addicted to amphetamine derivatives and cocaine. Sympathomimetics are strongly associated with aggressive behavior and street crime. Traumatic injuries are endemic among substance abusers and arise from both assault and motor vehicle collisions. Psychedelic drugs, such as LSD and PCP, can prompt extreme behavioral changes that can in turn lead to traumatic injuries. On occasion, trauma can be occult, and the unwary physician may overlook a stab wound in a patient whose clinical picture is predominantly drug-induced agitation.

DIAGNOSTIC ADJUNCTS

All patients with acute alterations in mental status in whom hypoglycemia is possible require either a finger-stick glucose test or the empirical administration of 50% dextrose solution. Patients who are unstable or with altered mental status may need evaluation of electrolytes, blood urea nitrogen, and creatinine. The electrocardiogram will occasionally diagnose a myocardial infarction in patients with drug-related chest pain as well as changes specific to certain drugs and medications, such as prolongation of the QRS or QTc interval. A complete blood cell count is of little value, except to follow serial hemoglobin values if occult trauma or hemolysis is suspected. Arterial blood gas analysis may be useful in assessment of acid-base status as well as in measurement of oxygenation and ventilation. Rhabdomyolysis, most often seen with psychostimulant abuse or prolonged periods in the same body position after abuse of sedatives (e.g., barbiturates), is best detected by measurement of serum creatine kinase or myoglobin.[33] Rhabdomyolysis is usually defined as creatine kinase levels more than five times the upper limit of normal, but absolute levels may not correlate with renal dysfunction. Dipstick urinalysis may screen positive for hemoglobin without accompanying red blood cells but is insensitive for this condition.

The use of qualitative toxicology screens is less important than the patient's history and clinical status. Although unsuspected drugs may be detected on a urine toxicology screen, this knowledge rarely affects acute management of the patient.[34,35] Quantitative levels of suspected substances, such as acetaminophen, acetylsalicylic acid, lithium, and certain anticonvulsants, may be valuable in certain circumstances. A new generation of rapid bedside "drug of abuse" urine toxicology screens may provide timely information, but their use requires further study.[36] There are some special circumstances in which rapid qualitative urine toxicology screening may have some utility. For example, positive urine screens for sympathomimetics can occasionally be found in children presenting with bizarre or abnormal behavior or new-onset convulsions if they have been exposed to these substances in the home environment where they are being used or manufactured. These findings in older children may also assist parents in assessing changing behavior or school performance in some situations.

MANAGEMENT

Agitation

Few antidotes exist for psychoactive drug intoxication, and with a few notable exceptions, treatment is supportive. Violent or agitated patients require rapid sedation. Benzodiazepines such as lorazepam (Ativan) can best sedate patients with sympathomimetic symptoms, whether they are due to drug intoxication or withdrawal. For other patients, intramuscular or intravenous butyrophenones, such as haloperidol (Haldol) and droperidol (Inapsine), are rapidly effective and generally safe. Droperidol has a box warning from the Food and Drug Administration (FDA) for QT prolongation and potentially torsades de pointes. However, in September 2007, the FDA added a warning that "torsades de pointes and QT prolongation have been observed in patients receiving haloperidol, especially when the drug is administered intravenously or in higher doses than recommended. Haloperidol is not approved for intravenous use."[37] Most reported cases of butyrophenone-induced dysrhythmias have been in individuals receiving large doses for prolonged periods, such as hours to days, or in elderly populations (older than 60 years). These medications lack the respiratory depression potentially caused by other agents and may be beneficial in some cases when sedation is required. For these reasons, the butyrophenones remain safe and effective agents for treatment of drug-induced agitation. In cases of cocaine or methamphetamine toxicity, in which hyperthermia or convulsions have occurred or can occur, benzodiazepines may be preferred. Phenothiazines, such as chlorpromazine, are not generally recommended in the drug-intoxicated patient because of their strong anticholinergic effects and potential to produce hypotension and lower the seizure threshold.

Body Packers and Stuffers

The body *stuffer* swallows loosely packaged drugs, or the raw drug itself, in an attempt to conceal contraband during arrest. The body *packer* (a "mule") delivers professionally packaged drugs in his or her intestinal tract, usually on a flight from another country. In many cases, these packets can be visualized radiographically.[38]

There is considerable debate about the best approach to these patients. Some sources recommend activated charcoal for body stuffers and whole-bowel irrigation for body packers, but others adopt a less aggressive approach.[39,40] In severe cases of body packing in which packet rupture occurs, surgical removal may be considered. In asymptomatic cases, the patient's right to refuse care usually supersedes local laws for forcible removal of such evidence, but patients who are significantly confused from drug effects (or comatose) are incapable of refusing lifesaving interventions.

Referral

After acute medical issues have been managed, substance abusers should be asked whether they would like help in overcoming their addiction. Studies show that intervention may be most successful for abusers of heroin, nonprescribed methadone, and benzodiazepines. Users of crack cocaine appear to be more resistant to treatment.[41] Offering symptomatic relief from withdrawal with short courses of medications including antiemetics, antidiarrheals, and benzodiazepines, when indicated, may improve the patient's ability to sustain sobriety.

Drug Seeker

As the front line in medical care, EDs are frequently confronted by patients with drug-seeking behavior, typically for pain medication or benzodiazepines. Although only 1% of ED patients have a formally recorded diagnosis of substance abuse, as many as 27% of ED patients are actually in need of substance abuse treatment.[42] This drug-seeking behavior is described as a compulsion for seeking and taking drugs after prolonged use of a certain drug.[43] Although health care providers should not facilitate drug-seeking

www.ketabpezeshki.com 66485457-66963820

behavior, inadequate pain management is internationally considered unethical.[44] Drug diversion has also become an increasing problem. The street value of prescription opioids such as oxycodone is greater than that of marijuana and heroin.[45]

Emergency physicians need to judiciously provide pain medication to avoid long-term problems from undertreatment of genuine acute pain. However, an overly liberal approach can contribute to addictive behavior. It is difficult for the individual health care provider to screen effectively for drug seeking or abuse on just a single encounter. Self-admission would be the easiest screen, but 90% of patients who abuse opioids deny it.[42] Although it is not sensitive, a prior history of drug or alcohol abuse may identify patients at risk for abuse of opioids, the most commonly abused agents of the prescription drug seeker.[46] Repeated visits for the same complaint, rapid dose escalation, unusual and multiple allergies, and demands for specific agents (often in specific milligram amounts) are all warning signs of potential drug seeking.[47] Unfortunately, there is no reliable finding that can consistently identify drug seeking while not penalizing those in true need of analgesics.

In response to this problem, both individual hospitals and some states are starting to track patients who habitually receive opioid prescriptions.[48] The effectiveness of such programs is not known. Some locales have had success with pain guidelines that restrict the use of opioids to proven conditions, with electronic flagging of habitual visitors who present for medical care.[47] Such approaches may work if they are done in conjunction with referral to chronic pain clinics or detoxification centers. A multifaceted approach that combined counseling, denial of narcotic prescriptions in the ED, and referral to a single pharmacy resulted in a 72% decrease in ED visits by frequent users.[49] Restriction or removal of meperidine from EDs can decrease visits from substance-abusing patients.[50]

Beyond facility-wide policies, individual physicians and other health care providers can attenuate drug-seeking behaviors. In addition, the conservative use of long-acting opioids, such as specialized forms of oral morphine, may decrease the reinforcement of drug-seeking behavior while providing compassionate pain alleviation.[51] Finally, pain contracts or explaining to the patient that opioids or other controlled substances are not appropriate may be helpful, but only if other physicians in the group or community agree on such a strategy for a particular patient.[45]

KEY CONCEPTS

- Substance abuse can affect people from all socioeconomic groups and all ages.
- For the majority of patients with toxin-induced violent behavior, intramuscular butyrophenones such as haloperidol (Haldol) are safe and rapidly effective sedating agents. With suspected sympathomimetic (e.g., cocaine and amphetamines) intoxication, benzodiazepines such as lorazepam (Ativan) should be used.
- Presentation to an ED with a complication of substance abuse may be a "teaching moment." Substance abusers should be offered drug treatment services.

Section Seven

THE DEVELOPMENTALLY OR PHYSICALLY DISABLED PATIENT

Chapter 187

Evaluation of the Developmentally or Physically Disabled Patient

Terry A. Adirim and Elizabeth D. Rosenman

PERSPECTIVE

Children and adolescents who are developmentally or physically disabled, have chronic illnesses, or are technology dependent for mobility or survival have special health care needs. The following definition of children with special health care needs (CSHCN) has become widely accepted within the pediatric community:

> *Children with special health care needs are those who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally.*[1]

The prevalence and characteristics of the CSHCN community depend on the definition used. With use of the federal definition derived by the Maternal and Child Health Bureau of 1998, a study analyzing data from 2006 to 2008 found that approximately one in six children in the United States experienced a special health care need.[2] There is a higher prevalence among older children, boys, and non-Hispanic white and black children, and after adjustment for demographic factors, families in poverty are more likely to have CSHCN.

Advances in medical science and technology have been instrumental in allowing children with complex medical problems to survive beyond the neonatal period. Moreover, family-centered care has been the goal for the care of these children, and as a result, many are living at home instead of in institutions.[3] CSHCN are frequent users of the emergency medical system. Emergency medical services are typically activated during the time of a crisis. This crisis may occur because of equipment failure or panic by the caregiver who is fatigued or new to caring for the child with special needs. However, a survey of 100 families with CSHCN conducted at a tertiary care urban pediatric center demonstrated that although 97% of the families had sought emergency care in the past, only 23% of the caregivers had ever called 911 before, and 93% had driven their child to the hospital during an emergency.[4] Families may transport their children either to the nearest community hospital or to their "home" institution, which is likely to be a tertiary care center. Most emergency medical service jurisdictions transport to the nearest "appropriate" medical facility.

Children (and youth) with special health care needs are usually cared for by adults who have been trained to manage their child's daily care. In general, families are knowledgeable about their child's medical conditions and technologic needs. Families may have detailed medical plans that specify such things as the size of tubes, how often to change tubes, dosages of medications, and ventilator settings. One example of a program that provides information to medical care providers is the Emergency Preparedness for Children with Special Health Care Needs program of the American Academy of Pediatrics and the American College of Emergency Physicians.[5] This emergency notification program's purpose is to communicate specific information to medical caregivers about the conditions and medications of a child or adolescent with special needs. An emergency information form is completed by the child's primary care physician or family and is carried with the child. Although most caregivers are adept at handling many of their children's emergencies, caregivers seek help for a variety of reasons, including the need for respite, equipment malfunction, an overwhelming medical problem, or help with transport to the child's home hospital.

In contrast to the pediatric population, there is no universally recognized definition for adults with special health care needs. The Institute of Medicine (IOM) has used several different definitions for disability, including an "inability or limitation in performing socially defined activity and roles expected of individuals within a social and physical environment."[6] The number of adults who meet this broad definition is difficult to calculate. Current estimates indicate that as many as 50 million U.S. residents have some type of disability.[7] Estimates come from various national surveys that vary in their definitions, questions, and target populations. Even more importantly, of 18 different national surveys reviewed by the IOM Committee on Disability in America, only four include institutionalized individuals.[7] Given the large number of surveillance groups, the IOM has recommended adoption of the World Health Organization's International Classification of Functioning, Disability and Health, which is currently being used in many countries as a standardized assessment tool for both individuals and populations.

Regardless of the definition used, patients with disabilities will have a wide spectrum of health care needs. Many individuals with mild disabilities are able to manage their medical needs independently or with minimal assistance from a primary health care provider, whereas others require frequent and even continuous interactions with the health care system. An individual's needs will probably change over time as well. Many of the childhood conditions that are associated with special health care needs, such as cerebral palsy, will persist into adulthood. The relative incidence of traumatic injury is highest among adolescents and young adults, making traumatic brain and spinal cord injuries a significant contributor to both physical and cognitive disability. In the aging population, vascular disease becomes more common, including cerebrovascular accidents and amputations secondary to peripheral vascular disease and diabetes. Finally, dementia, movement disorders, and general deconditioning are prevalent among the elderly population.

DISTINGUISHING PRINCIPLES OF DISEASE

General Issues for Children and Youth with Special Health Care Needs

CSHCN differ from other children in a variety of ways. Some CSHCN may be neurologically impaired and therefore have intellectual disabilities. Their physical growth may be limited, resulting in stature smaller than that of other children of the same age. As a result, medical personnel cannot rely on age- and weight-based norms and should either ask caregivers for this information or use length-based tapes to estimate weight, to calculate drug dosages, and to determine fluid management. Children and adolescents with chronic health conditions may have vital signs that differ from those expected for children without chronic conditions of the same age.[4] For example, baseline vital signs are altered in children with cardiac conditions or who are on mechanical ventilators. A child with an unrepaired complex congenital heart defect may have a baseline pulse oximetry reading in the low 80s. Some children with lung diseases may have respiratory rates higher than expected, yet these higher respiratory rates are considered their baseline.[4] Also, some children may have sensorineural deficits, such as blindness and deafness, that may make history taking and physical assessment challenging. Medical care providers need to be cognizant of these differences.

Care should be taken when children with physical or cognitive disabilities are treated and moved as they may become frightened easily with quick motions and unfamiliar sights and sounds. Use of a calming tone while speaking at a developmental level the child can comprehend can decrease anxiety and most likely increase cooperation. Allowing parents to be at the bedside is vital for all children but most especially for these children. Moving of children with musculoskeletal disorders can best be accomplished with slow, deliberate motions so as not to frighten the child. The child's caregivers are the best resource in determining the most appropriate methods for communicating with or moving a child with special needs.

General Issues for Adults with Special Health Care Needs

Adults who have suffered a neurologic insult, whether it is congenital, traumatic, or medical, may have communication limitations ranging from mild to severe. A wealth of information may be provided by contacting the nursing facility from which a patient was transferred or calling a family member at home. Equally important is identification of any special communication devices, such as a Passy-Muir (speaking) valve or a writing board, that will facilitate the history-taking process and empower the patient.

Weakness, paralysis, pain, and spasticity can contribute to impaired mobility and make the physical examination challenging. Patients may be reluctant or unable to get out of their wheelchair or to get undressed. This can be a time-consuming and frustrating process in a busy emergency department (ED). Enlistment of help from ancillary staff can expedite this process and ensure the patient's safety.

Patients with special health care needs often have indwelling catheters and implanted devices. It is important to ask about these as complications are not infrequent. Catheters can fall out or become clogged, and implanted devices can malfunction or migrate. Furthermore, anywhere there is a foreign body, there is increased risk of infection.

For all patients and especially those with impaired communication, limited mobility, or indwelling or implanted devices, it is crucial to perform a meticulous physical examination. A patient with a fever and cloudy urine may also have a rectal abscess or erythema around a dialysis catheter that could easily be overlooked if a thorough physical examination is not routinely performed.

SPECIFIC DISORDERS

Airway and Pulmonary Conditions

Tracheomalacia

Tracheomalacia is a condition of abnormally weak tracheal walls due to the loss of supporting cartilage and structural integrity. This frequently causes collapse of the trachea on inspiration. Tracheal collapse is most prominent during times of increased airflow, such as when the infant is coughing, crying, or feeding or has an upper respiratory infection.

There are three causes of tracheomalacia: congenital or intrinsic tracheal anomaly (occurring within the trachea), which may be associated with a tracheoesophageal fistula (a patent connection between the trachea and esophagus); extrinsic defects (occurring outside the trachea), such as abnormal development of the vasculature around the trachea that may create a ring, which places pressure on the trachea and interferes with airflow; and acquired malacia, which occurs in children with prolonged intubation or chronic tracheal infections.[8]

Medical management for tracheomalacia consists of symptomatic treatment. A child may experience respiratory compromise with simple viral infections. Racemic epinephrine may decrease swelling of the upper airway under these circumstances. It is prudent to observe these children in the hospital until they are no longer compromised. For children with severe tracheomalacia, a stent or rigid piece of cartilage may be surgically placed in the collapsed area of the trachea to establish permanent patency. Infants with vascular rings have varying degrees of tracheal compromise. Treatment of constricting vessels consists of surgical division and reattachment to surrounding structures to release the pressure on the trachea. In rare instances, tracheostomies are placed to provide a patent airway until the child's airway grows and strengthens. Fortunately, most infants with tracheomalacia require no specific treatment, and over time the airway grows and the condition improves.

Regardless of the underlying cause, infants and children with tracheomalacia who are in respiratory distress present with similar signs and symptoms. These include cough, prolonged expiratory phase, stridor, accessory muscle use, and hypoxia.

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD), a chronic lung disease occurring in infants, is characterized by poor lung compliance and chronic exacerbations. BPD is a worldwide problem, with 5000 to 10,000 new cases reported each year. BPD, cystic fibrosis, and asthma are the three most common chronic lung diseases in infants.[9]

BPD develops primarily in low-birth-weight infants who have respiratory distress syndrome. Babies born before 32 weeks' gestation may not have enough surfactant to keep their alveoli open.[10] However, BPD development is not limited to survivors of respiratory distress syndrome. BPD may result from alveolar damage caused by other lung diseases, exposure to prolonged high oxygen concentrations, use of mechanical ventilation after birth because of conditions such as neonatal pulmonary hypertension and pneumonia or other infections, or trauma to the lungs.[10]

A combination of fewer air sacs and a lack of surfactant can result in abnormally stiff lungs. This increases the work of breathing for affected infants, who can quickly become fatigued. Respiratory infections can also worsen the inflammatory response in the

www.ketabpezeshki.com 66485457-66963820

lungs, leading to more fluid in the lungs and bronchospasm. Signs and symptoms of BPD can vary in severity by the infant's lung maturity. They may include tachypnea, retractions, paradoxical respirations, abnormal posturing, and wheezing.

BPD causes the most difficulties during the first year of life, which is when most deaths from this disorder occur. The most common long-term lung complication of BPD is asthma, which occurs in approximately half of patients. Other less common complications include apnea during infancy, gastroesophageal reflux, pulmonary hypertension, high blood pressure, pulmonary edema, aspiration, subglottic stenosis, and tracheomalacia. Infants who have BPD are at risk for frequent hospitalizations because of their borderline respiratory reserve, hyperactive airway, and increased susceptibility to respiratory infection.

Treatment of BPD involves symptomatic relief. Home management may include oxygen, bronchodilators, corticosteroids, diuretics, antibiotics, and, in rare cases, ventilator support through a tracheostomy.

Apnea

Apnea in infants and young children is defined as a cessation in breathing for more than 20 seconds or associated with a change in color, limpness, altered mental status, or bradycardia. Apnea occurs more frequently in infants born prematurely and generally reflects immature neurologic and respiratory control mechanisms.[11] These pauses in respiration may be due to central apnea, which is the result of an absence of a neurologic signal to the respiratory muscles. Underlying causes include encephalitis, brainstem infarction or tumor, neuromuscular disorders such as muscular dystrophy, and thoracic restrictive disorders such as kyphoscoliosis. These children are discharged home from the hospital on an apnea monitor. Apnea monitor alarms often result in ED visits. The apnea monitor should be transported with the child to the hospital. Most monitors contain a computer chip that records information that can be downloaded into a computer at the child's regular hospital (home hospital) to determine the origin of the monitor alarms (high or low heart rate, apnea, or artifact).

The most common type of childhood apnea is obstructive apnea, which is caused by an occlusion in the upper airway at the oropharyngeal level or by gastroesophageal reflux disease. Gastroesophageal reflux disease occurs when the lower esophageal sphincter opens, causing stomach contents to pass into the esophagus during or after a meal. Younger children tend to outgrow this condition. Those who continue to be symptomatic can experience complications such as a chronic cough, recurrent pneumonia, difficulty in swallowing, recurrent vomiting, and weight loss. Symptoms can often be controlled with positioning, diet, medications, and, in rare circumstances, surgery.

Mixed apnea is central apnea that is followed by an obstructive apnea event. Obstructive sleep apnea may be managed by providing oxygen during sleep or through continuous positive airway pressure (CPAP), which may be delivered through a nose mask or tracheostomy. Central apnea is managed with supplemental oxygen and CPAP but also responds to medications that stimulate the respiratory system or mechanical ventilation.

Apnea in adults is most frequently related to obstructive sleep apnea. This can be due to altered oropharyngeal anatomy but is most commonly secondary to obesity. Decreased muscle tone during sleep leads to obstruction of the pharynx and hypopharynx with redundant tissue. Central sleep apnea is also seen in patients with heart failure. Regardless of etiology, sleep apnea can result in mild to severe sleep disturbances leading to daytime somnolence and irritability. It is also associated with significant morbidity and mortality, including heart failure, acute coronary syndrome, cerebrovascular accidents, and death.[12-15] Like pediatric obstructive apnea, obstructive sleep apnea in adults is treated with noninvasive positive-pressure ventilation, such as CPAP, during sleep.

Chronic Respiratory Failure in Adults

A wide range of disorders can lead to chronic respiratory failure in adults. These can be divided into three broad categories: intrinsic lung disease, central nervous system disease, and neuromuscular disorders. One of the most common causes of lung disease and chronic respiratory failure in adults is chronic obstructive pulmonary disease (COPD), which is usually due to long-term tobacco exposure. A patient with mild COPD may be managed with inhaled bronchodilators and anticholinergics. With disease progression, patients may require supplemental oxygen at home and may have substantial disability secondary to exertional dyspnea. In the evaluation of a patient with COPD, it is important to ask about home oxygen requirements and baseline oxygen saturation.

Patients with COPD may present in respiratory distress secondary to an exacerbation of their underlying disease. COPD is an obstructive process; people with severe disease will often have elevated carbon dioxide levels at baseline (carbon dioxide retainers), and respiratory drive is often dependent on arterial oxygen concentrations rather than on carbon dioxide concentrations. Attempting to correct oxygen saturation to 100% can decrease the patient's inherent respiratory drive and result in further carbon dioxide retention and altered mental status secondary to hypercarbia (carbon dioxide narcosis). Other common reasons for ED visits include bronchitis and pneumonia. Finally, patients may run out of their oxygen or have an equipment malfunction. A social worker, if available, can assist in coordinating replacement of supplies and ensuring that the patient has a reliable source for home oxygen.

Other less common causes of lung disease include bronchiectasis, sarcoidosis, fibrosis, α_1-antitrypsin deficiency, and pulmonary hypertension. These all have specific management issues, and it is helpful to involve the patient's pulmonologist whenever possible. Individuals with chronic lung disease, regardless of the etiology, may have significant functional limitations related to dyspnea and deconditioning. In an otherwise well-appearing patient, ambulation can reveal hypoxia and dyspnea that may be missed on initial evaluation.

Central nervous system disorders can result in respiratory failure secondary to impaired or absent neurologic control or respiratory muscle weakness or paralysis. The initiation and coordination of respiratory effort is complex and involves multiple areas within the brainstem. Brainstem lesions can result in central apnea or asynchronous respiratory efforts and generally require tracheostomy and mechanical ventilation. The diaphragm is innervated by C3-5 and the intercostal muscles are innervated by T1-7, so cervical and thoracic cord lesions can result in respiratory muscle weakness. The severity of weakness depends on the level and nature of the lesion, with higher and more complete lesions causing more severe impairment. Examples of spinal cord lesions include traumatic cord injuries; compressive lesions, such as spinal cord hematomas and abscesses; and intrinsic cord disease, such as transverse myelitis.

Myasthenia gravis is a neuromuscular disorder that can cause respiratory insufficiency and failure. Myasthenia gravis is an autoimmune process that attacks the postsynaptic acetylcholine receptors at the neuromuscular junction. It most commonly affects the bulbar muscles but can also result in generalized weakness.[16] Other neuromuscular disorders that can affect the respiratory muscles include muscular dystrophy, multiple sclerosis, and amyotrophic lateral sclerosis. In any patient with respiratory muscle weakness secondary to a neuromuscular disease, pulmonary function tests are an important component of the assessment. One test that can

www.ketabpezeshki.com 66485457-66963820

rapidly be obtained in the ED is a negative inspiratory force or maximal inspiratory pressure. A value of less than 20 cm H_2O is the generally accepted cutoff for severe impairment and can help determine which patients need ventilatory support. This test is usually performed by a respiratory therapist with use of a pressure gauge connected to a disposable mouthpiece.

Finally, there are a few conditions that do not fall into any of the prior categories but that can cause respiratory insufficiency and hypoventilatory respiratory failure by restricted chest wall expansion. Examples are severe scleroderma and morbid obesity.

For all causes of chronic respiratory insufficiency, affected individuals will fatigue more rapidly when they are faced with any new pulmonary insult and may rapidly progress to respiratory failure. Any of these disease processes may require tracheostomy and mechanical ventilation because of either baseline respiratory insufficiency or the frequency of exacerbations leading to respiratory failure.

Tracheostomy Tubes

Tracheostomy tubes are placed to facilitate mechanical ventilation, to provide a bypass of the upper airway, or to keep the airways clear of secretions. The more common conditions for which tracheostomy tubes are placed include tracheal stenosis, tracheomalacia, certain craniofacial anomalies, BPD, muscular dystrophy, spinal cord injury or disease, traumatic or anoxic brain injury, and cerebrovascular accidents.[8]

Because the tubes are available from several manufacturers, their sizing and markings vary. Common brands are Shiley, Bivona, Hollinger, Portex, and Bardeen. Typically, the sizes are marked on the packaging and on the flange, or wings, of each tube. They range in size from 00 for newborns to 7.0 for older adolescents and adults. The inner and outer diameter ranges are provided so that comparisons between brands can be made. They range from 2.5 mm for infants to 10.0 mm for adolescents and adults. This information is helpful for emergency personnel in replacing a tracheostomy tube or in choosing an endotracheal tube for oral intubation or use through a stoma. The inner diameter of a tracheostomy tube should be used to choose the endotracheal tube size for insertion through a stoma. Tracheostomy tubes also come in various lengths. Neonatal tubes are shorter than pediatric tubes, although the inner diameters may be the same.[8]

There are several types of tracheostomy tubes and attachments: single-cannula tubes (Fig. 187-1), double-cannula tubes (Fig. 187-2), cuffed tubes (Fig. 187-3), and fenestrated tubes (Fig. 187-4).[8] Neonates, infants, and young children use single-cannula tracheostomy tubes. A double-cannula tube can be used in older children and adults. It contains an outer tube that stays in the stoma and an inner tube that is removable for cleaning and pulmonary toilet. Tracheostomy tubes for older children and adults have an inflatable cuff to keep the tube in place and to prevent air leaks. Fenestrated tubes have a hole in the cephalic portion of the tube that redirects air into the upper airway to allow the individual to speak and to breathe through the nose and mouth. This is facilitated by a decannulation plug that is attached to the opening of the tube.

Attachments to the tracheostomy tube may include a tracheostomy nose, a tracheostomy collar, and a speaker valve. A tracheostomy nose is placed over the external opening of the tracheostomy tube of a nonmechanically ventilated person to provide air filtration and humidification. Likewise, a tracheostomy collar is used to provide humidified air or supplemental oxygen to the nonmechanically ventilated patient. A speaker valve is an attachment that redirects airflow through the upper airway to facilitate speech.

Individuals with tracheostomy tubes seek emergency care for four primary reasons: exacerbation of the underlying pulmonary disease, blockage of the tube by a mucous plug, equipment failure, and dislodgement of the tracheostomy tube. Signs and symptoms of respiratory distress include nasal flaring, retractions, increased respiratory rate, decreased breath sounds, decreased oxygen saturation, cyanosis, wheezing, rales, and increased secretions.

Sudden onset of respiratory distress may suggest a mucous plug or equipment failure rather than a pulmonary infection, which is usually heralded by a more progressive deterioration of respiratory status and fever. Airway assessment should include inspection of the tracheostomy tube for patency.

In a patient experiencing an exacerbation of pulmonary disease, infection and reactive airway disease are the most likely possibilities. Acute treatment of wheezing includes administration of a

bronchodilator by nebulizer through the tracheostomy or in-line with the ventilator if the patient is mechanically ventilated. In a patient presenting with a fever or an increase in secretions, infection should be considered. Chest radiography should be obtained. Tracheostomy cultures are controversial given high rates of bacterial colonization of tracheostomy tubes. Early antibiotic coverage is indicated if pneumonia is suspected. The need for hospitalization is determined by a combination of factors including age, medical history, severity of illness, and diagnosis.

For sudden onset of respiratory distress, suctioning of the tracheostomy tube may be helpful. Approximately 2 to 3 mL of normal saline should be instilled before suctioning. If suctioning two or three times does not relieve the obstruction or respiratory distress, the medical provider should change the tracheostomy tube because there may be a thick mucous plug obstructing airflow through the tube. An endotracheal tube can be used as a substitute if the appropriate size of a tracheostomy tube is not available. For patients cared for at home, the parents or caregivers often have spare equipment in their "go" bags that can be used (for troubleshooting, see Tables 187-1 and 187-2).

Home Mechanical Ventilation

Many individuals with tracheostomy tubes are also mechanically ventilated. Indications for mechanical ventilation include severe lung disease and abnormal respiratory drive either from central causes or secondary to weakness or paralysis. Some people are dependent on ventilators continuously; some depend on ventilators while they are asleep, others for part of the day.[11]

There are two types of ventilators: pressure-cycled ventilators and volume ventilators. Pressure-cycled ventilators tend to be used in infants. They are set to deliver a given pressure with each breath. Volume ventilators give a tidal volume with each breath. There are two common modes of ventilations: intermittent mandatory ventilation and controlled mechanical ventilation. Intermittent mandatory ventilation mode delivers a mechanical breath between the patient's own respirations to ensure that the patient achieves a certain number of breaths per minute. In this mode, the ventilator can synchronize its breaths with the patient's breaths. On the other hand, with controlled mechanical ventilation, the ventilator is set to deliver a certain number of breaths per minute whether or not the patient can breathe without assistance. Some ventilators have an assist-control mode in which the ventilator gives a breath at the same time the patient takes a breath to augment the patient's effort.[8]

There are five types of home ventilator alarms: low pressure/apnea, low power, high pressure, setting error, and power switchover. The causes of a low-pressure alarm include a loose or disconnected circuit, a leak in the circuit, and a leak around the tracheostomy site. The low-power alarm indicates that the internal battery is near completion and the ventilator will need to be plugged into an electrical outlet. A high-pressure alarm indicates that there is an obstructed circuit or increased airway pressures. Increased airway pressure can result from any type of lung disease, including bronchospasm, pneumothorax, infection, and pulmonary edema. A setting-error alarm indicates that the setting has been improperly adjusted. Under these circumstances, the patient should be manually ventilated until the ventilator can be set properly. The power-switchover alarm sounds whenever the ventilator switches from AC power to battery power. When this happens, check to ensure that the battery is powering the unit before pressing the "alarm silent" button.[8]

Possible causes of respiratory distress in a ventilator-dependent individual include airway obstruction (e.g., obstructed tracheostomy tube), obstruction or leak in the ventilator tubing, problems with the oxygen supply, equipment failure involving the ventilator, and a medical condition. If a ventilator-dependent patient is found to be in respiratory distress and the cause is not easily determined, the patient should be taken off the ventilator promptly and ventilated with a manual resuscitator (bag-mask ventilation device). Manual ventilation of the patient can help determine if the equipment has failed or a medical condition is responsible.

Neurologic Conditions

Cerebral Palsy

Cerebral palsy (CP) is the leading cause of childhood disability,[17] and population studies have shown that more than 80% of children with CP will survive into adulthood.[18] CP is a group of disorders affecting the development of movement attributed to nonprogressive disturbances that occur in the developing fetal or infant brain. The motor disorders are often accompanied by one or more of the following: disturbances of sensation, cognition, communication, perception, or behavior or a seizure disorder.[19] Premature birth is the most common associated historical factor, and prenatal maternal infection and multiple pregnancies have also been associated with CP.[17]

CP is classified on the basis of the type of movement disorder and the area of the body involved: spastic, athetoid, ataxic, or mixed and hemiplegia, diplegia, or quadriplegia. The most common form, spasticity, is defined as a velocity-dependent resistance to stretch. When the extremities of an individual with the spastic form of CP are stretched beyond their range of motion,

Table 187-1 Medical Devices: Common Problems and Solutions

DEVICE	PROBLEM	ACTION
Tracheostomy	Obstruction	Attempt assisted ventilation with high-concentration oxygen. Attempt to suction. Change tracheostomy tube. Ventilate through stoma.
	Dislodged	Replace tracheostomy. Provide assisted ventilation with high-concentration oxygen through the stoma.
	Unable to reinsert	Attempt to place a tracheostomy tube one size smaller. If attempt fails, attempt to place a similar size endotracheal tube. If attempt fails, provide assisted ventilation through stoma or through the child's mouth while blocking the stoma.
Home ventilator	Respiratory distress	Ask parents to check whether ventilator is functioning properly. Assist in adjustment of ventilator. Assess tracheostomy for obstruction. Remove patient from ventilator and provide assisted ventilation.
Pacemaker	Failure	Assess heart rate and perfusion. Treat for shock. Follow appropriate PALS guidelines.
Central intravenous catheter	Dislodged or damaged	Apply direct pressure to stop bleeding. Clamp or tie exposed catheter to prevent further blood loss. Assess and treat patient for hemothorax and shock.
	Air embolism	Clamp the line. Place patient on left side with head down. Administer high-flow oxygen.
Central venous catheter site	Signs of infection at the site	Treat as a potentially serious infection.
Oral or nasal feeding catheter	Dislodged	Remove catheter. Have patient seek medical attention for tube reinsertion.
Surgically placed feeding catheter	Dislodged	Cover open stoma with gauze.
	Abdominal distention or obstruction	Unclamp tube. Decompress stomach (aspirate air or fluids).
CSF shunt	Failure or obstruction	Treat ABCs. Keep head elevated. Give anticonvulsants for seizure activity. Follow appropriate PALS guidelines for arrhythmias.

Modified from Adirim T, Smith E: Special Children's Outreach and Prehospital Education. Sudbury, Mass, Jones and Bartlett, 2006.
ABCs, airway, breathing, and circulation; *CSF,* cerebrospinal fluid; *PALS,* pediatric advanced life support.

the muscles contract and increase resistance. Clonus and persistent primitive reflexes are characteristic. Because CP is a movement disorder, gross motor skills are delayed. There is a lack of coordination and differential strength and tone in the musculature of the individual. Treatment is focused on management of spasticity. Some of the treatments include daily range-of-motion exercises, casting, and splinting. Some people may take oral medications (baclofen, diazepam, and clonidine) to improve muscle spasticity or to decrease the drooling that is evident in 10% of children with CP, caused by poor oromotor control combined with decreased sensation and poor head control.[18]

Some individuals with CP are now treated with baclofen pumps inserted directly into the thecal sac surrounding the spinal cord. Baclofen is directly infused into this space by a small pump through continuous infusion. Baclofen acts by binding to receptors in the spinal cord, thereby inhibiting spinal reflexes. Complications include overdose when the pump is filled incorrectly or programming is inaccurate. Overdose can lead to respiratory depression and death. Some less serious side effects of the medication are drowsiness, dizziness, hypotension, headache, and nausea. The physician presented with a comatose patient with CP on a baclofen pump must maintain the patient's airway, breathing, and circulation until the pump is urgently stopped with a specialized device. If this device is not readily available, emptying of the reservoir with a 22-gauge needle is an alternative treatment. This can be done by locating the pump in the abdominal wall and inserting the needle in the center of it. Another complication is medication withdrawal due to pump failure, which is usually the result of tube obstruction or faulty pump programming. Symptoms of withdrawal include increased spasticity, tachycardia, blood pressure changes, severe hyperthermia, and rhabdomyolosis.[19,20]

Intellectual Disability

Intellectual disability, previously known as mental retardation, is commonly found in both children and adults. Approximately 30 to 50% of individuals with CP have significant intellectual disabilities. Most have milder cognitive deficits and learning disabilities, and some individuals with CP have normal intelligence. Other causes of intellectual disability include prenatal and perinatal exposures, traumatic or anoxic brain injuries, and genetic syndromes. The term *developmental delay* is often used interchangeably with mental retardation and intellectual disability. Mental retardation has a specific definition, however. Mental retardation is a fixed disability characterized by significant limitations both in intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills.[21] Developmental delay is a failure to achieve age-appropriate milestones; these children have the potential to "catch up" and eventually to progress normally with their growth and development. In all situations, it is important to assess the developmental level of the patient as well as associated problems, such as hearing or visual impairment.

www.ketabpezeshki.com 66485457-66963820

Table 187-2 Troubleshooting Gastrostomy Tubes and Buttons

PROBLEM	POSSIBLE CAUSATION	ACTIONS
Nausea, vomiting, cramping, or diarrhea	Too rapid feeding Feeding too cold Spoiled formula or a change in formula	Increase feeding time. Ensure that feeding is at room temperature.
Leakage of stomach contents	Mechanical Broken or sticking valve Malpositioned tube wedged into the gastric mucosa Balloon not inflated properly Organic Increased volume of feeding (too much gas or formula) Constipation Ileus Pneumonia (from coughing), seizures	Place insertion obturator, decompression tube, or 8- to 10-Fr suction catheter into shaft of button so it moves the flex valve. The anti-reflux valve makes a popping sound when it moves back into closed position. Ensure that the balloon is fully inflated. Check stomach residual; readjust method of feedings as appropriate. Evaluate for other organic causes and treat accordingly.
Blockage of button	Feeding or medications too thick or remain in shaft too long	Flush button with 5-10 mL of tap water after use. Use thin solutions with well-crushed medications. Use insertion obturator or 8- to 10-Fr suction catheter to gently try to push the plug through.
Accidental removal of button	Vigorous pulling on the button Spontaneous deflation of the gastrostomy balloon	Insert gastrostomy tube to keep stoma open. As a last resort, a Foley catheter with an anti-migration device may be inserted into the stoma. The tube must be securely taped in place. Immediately transport to tertiary hospital for button replacement. Button length may be too long.
Stoma site irritation Maceration due to moisture Gastric acid burn from leakage of gastric contents Purulent mucus	Regular cleaning not effective Incomplete drying Feeding spillage with incomplete cleaning Leakage of gastric contents from or around tube Excessive granulation tissue	Button length may be too short. Do not use occlusive dressing, gauze, tape, or creams. Rotate button 360 degrees once a day. Clean site daily with soap and water. Clean site with ⅓-strength hydrogen peroxide if it is irritated. Consider use of a skin barrier cream and H_2 blocker for gastric burns.
Balloon leaks or ruptures	Silicone balloons generally last about 3 months; however, life of balloon may vary	Replace gastrostomy button.

Autism and Other Neurodevelopmental Disorders

The 2007 National Survey of Child Health estimates that there are 673,000 children in the United States with autism spectrum disorders, and data from the 2006 Autism and Developmental Disabilities Monitoring Network estimate the prevalence of autism to be 1% of all children in the United States.[22,23] Autism spectrum disorders are a group of neurodevelopmental disorders characterized by impaired development in socialization, communication, and behavior. These disorders include autism, Asperger's syndrome, and pervasive developmental disorder, not otherwise specified. Studies have shown that these children have a high level of functional limitations and poor health status, an accompanying high level of health care use and unmet health needs, and increased parenting stress and family burden.[24-26] In fact, a Pennsylvania Autism Needs Assessment from September 2011 reported that both the untreated or undertreated symptoms of autism and co-occurring disorders can result in unwanted outcomes, including police contact, ED visits, and inpatient psychiatric hospital care, and that the incidence of these outcomes increases markedly with age from less than 5% of children to more than 10% for ED visits to almost 25% for police contacts in adults with autism. The most common reasons for emergency and inpatient hospital-based care are aggression and defiant behaviors, followed by self-injury, anxiety, and depression.

More than 40% of children and adolescents with autism and other neurodevelopmental disorders have multiple conditions. For children with autism, more than 95% have a co-occurring developmental disorder, such as attention deficit disorder, attention-deficit/hyperactivity disorder, learning disabilities, mental retardation, stuttering, and other developmental delays.[24] Also, children with autism have a higher incidence of seizure disorders. Therefore, children with autism are more likely to be taking prescription medications and to access health care services at higher rates than normal children do.

Working with these children, adolescents, and adults in the ED presents a number of challenges because of their impaired communication skills, intellectual disability, and co-occurring psychiatric conditions. Determine the patient's level of cognitive function and tolerance for new places and people by talking to the caretaker. Engage the family in the care of the patient to lessen the patient's anxiety. Avoid forcing the patient to submit to an examination or to undergo a diagnostic procedure. Speak softly and reassuringly and speak directly to the patient. With the family, ascertain the cause of the patient's distress because uncontrolled behaviors could be due to a medical condition or a response to pain.

Strategies typically used to treat aggression and other behavioral disorders are often less effective in people with autism. Consultation with specialists with knowledge of the care of people with autism is recommended (e.g., specialists at regional tertiary care centers). Children with autism spectrum disorders with aggressive behaviors not controlled by behavioral therapy are increasingly being treated with atypical antipsychotic agents, such

www.ketabpezeshki.com 66485457-66963820

as risperidone.[27] Management of uncontrolled behavior may necessitate medication, especially to protect patients from harming themselves or others.

Seizures

Seizure disorders affect approximately 10% of children who are disabled, compared with only 0.5% of healthy children. The frequency of seizure disorders in adults is more difficult to estimate as adults have less consistent health care and are more likely than children to have seizures secondary to other medical or toxicologic issues. In a 2004 nationwide survey, 2.9% of participants reported a diagnosis of epilepsy or seizure disorder.[21] Patients with seizure activity often have normal intelligence, and their seizures can be well controlled by anticonvulsant medication.[28] With age comes an increasing frequency of secondary seizure syndromes, such as post-traumatic seizures, adverse reactions to medications, and seizures related to structural lesions such as masses, or encephalomalacia. In someone receiving antiepileptic therapy with stable symptoms, a "breakthrough" seizure may occur as a result of toxic or subtherapeutic blood levels of seizure medication. This may occur for a variety of reasons. These include but are not limited to poor absorption of the medication secondary to a gastrointestinal illness, missing of one or more doses of anticonvulsant medication, medication dosages not being appropriately adjusted for a patient's growth or weight gain, and lowered seizure threshold from an illness or accidental multidosing of a patient's medication (Table 187-3). For patients with multiple abnormalities, seizure activity is generally more severe and is more difficult to control with anticonvulsant medications.

Table 187-3 Antiseizure Medications, Their Side Effects, and Examples of Drugs Interfering with Serum Concentration

BRAND NAME (GENERIC NAME)	POSSIBLE SIDE EFFECTS	DRUGS INCREASING SERUM CONCENTRATION	DRUGS DECREASING SERUM CONCENTRATION
Ativan (lorazepam)	Drowsiness, sleepiness, fatigue, poor coordination, unsteadiness, behavior changes		Carbamazepine, phenobarbital, phenytoin, primidone
Banzel (rufinamide)	Drowsiness, attention difficulty, headache, fatigue, loss of appetite, vomiting, dizziness, irritability, itchiness, stomach pain		
Carbatrol (extended-release carbamazepine)	Dizziness, drowsiness, blurred or double vision, nausea, rashes, abnormal blood counts (rare)	Felbamate, valproic acid Fluoxetine, trazodone Clarithromycin, erythromycin, fluconazole, isoniazid, ketoconazole, metronidazole Cimetidine, danazol, diltiazem, risperidone, verapamil	May reduce the efficacy of oral contraceptives
Depakene (valproate)	Upset stomach, altered bleeding time, liver toxicity, hair loss, weight gain, tremor	Felbamate, sertraline, isoniazid, cimetidine	
Depakote (divalproex sodium)	Upset stomach, altered bleeding time, liver toxicity, hair loss, weight gain, tremor		
Depakote ER (extended-release divalproex sodium)	Hair loss, upset stomach, tremor, altered bleeding time, liver toxicity, weight gain, headaches, drowsiness, dizziness, blurred or double vision, twitching		
Diamox (acetazolamide)	Appetite loss, frequent urination, drowsiness, confusion, extremity numbness, kidney stones		
Diastat AcuDial (diazepam rectal gel)	Drowsiness, sleepiness, fatigue, poor coordination, unsteadiness, behavior changes		
Dilantin (phenytoin)	Clumsiness, insomnia, motor twitching, nausea, rash, gum overgrowth, hairiness, thickening of features	Felbamate, oxcarbazepine, sulthiame, valproic acid Fluoxetine, fluvoxamine, imipramine, sertraline, trazodone, viloxazine Chloramphenicol, fluorouracil, tamoxifen, tegafur, UFT Allopurinol, amiodarone, cimetidine, diltiazem, omeprazole, tacrolimus	May reduce the efficacy of oral contraceptives
Felbatol (felbamate)	Anorexia, vomiting, insomnia, nausea, headache, liver and blood toxicity		May reduce the efficacy of oral contraceptives
Gabitril (tiagabine)	Tremor, dizziness, nervousness, difficulty concentrating, sleepiness, weakness		
H.P. Acthar gel (ACTH [adrenocorticotropic hormone])	Insomnia, increased appetite, weight gain, irritability, fluid retention

Table 187-3 Antiseizure Medications, Their Side Effects, and Examples of Drugs Interfering with Serum Concentration—cont'd

BRAND NAME (GENERIC NAME)	POSSIBLE SIDE EFFECTS	DRUGS INCREASING SERUM CONCENTRATION	DRUGS DECREASING SERUM CONCENTRATION
Keppra (levetiracetam)	Sleepiness, fatigue, poor coordination, loss of strength, dizziness		
Klonopin (clonazepam)	Drowsiness, sleepiness, fatigue, poor coordination, unsteadiness, behavior changes		
Lamictal (lamotrigine)	Dizziness, headache, blurred vision, clumsiness, sleepiness, nausea, rash	Valproic acid, sertraline	May reduce the efficacy of oral contraceptives
Lyrica (pregabalin)	Weight gain, blurred or double vision, dry mouth, difficulty concentrating, dizziness, swelling of hands and feet, sleepiness, drowsiness		
Mysoline (primidone)	Clumsiness, dizziness, appetite loss, fatigue, drowsiness, hyperirritability, insomnia, depression, hyperactivity (children)		May reduce the efficacy of oral contraceptives
Neurontin (gabapentin)	Sleepiness, dizziness, clumsiness, fatigue, twitching		
Phenobarbital (phenobarbital)	Drowsiness, irritability, hyperactivity (children), behavioral problems, difficulty concentrating, depression	Felbamate, phenytoin, sulthiame, valproic acid, chloramphenicol	May reduce the efficacy of oral contraceptives
Sabril (vigabatrin)	Vision loss, abnormal magnetic resonance imaging scans, anemia, sleepiness, numbness of extremities, weight gain, swelling, hyperactivity		
Tegretol (carbamazepine)	Dizziness, drowsiness, blurred or double vision, nausea, rashes, abnormal blood counts (rare)		May reduce the efficacy of oral contraceptives
Tegretol XR (extended-release carbamazepine)	Dizziness, drowsiness, blurred or double vision, nausea, rashes, abnormal blood counts (rare)		May reduce the efficacy of oral contraceptives
Topamax (topiramate)	Confusion, sleepiness, dizziness, clumsiness, difficulty thinking or talking, tingling sensation of the skin, nausea, decreased appetite		May reduce the efficacy of oral contraceptives
Tranxene (clorazepate)	Drowsiness, sleepiness, fatigue, poor coordination, unsteadiness, behavior change		
Trileptal (oxcarbazepine)	Difficulty concentrating, sleepiness, fatigue, dizziness, double vision, nausea, unsteadiness, rash		May reduce the efficacy of oral contraceptives
Zarontin (ethosuximide)	Appetite loss, nausea, drowsiness, headache, dizziness, fatigue, rash, abnormal blood counts (rare)	Isoniazid	
Zonegran (zonisamide)	Sleepiness, dizziness, loss of appetite, headache, nausea, irritability, difficulty concentrating, unsteadiness, fever, kidney stones, rash (should not be used in individuals allergic to sulfa drugs)		

Modified from the Epilepsy Foundation, Western/Central Pennsylvania: Anti-seizure medication and their side effects. Available at www.efwp.org/programs/side_effects.shtml. Accessed November 25, 2011; and Perucca E: Clinically relevant drug interactions with antiepileptic drugs. Br J Clin Pharmacol 61:246-255, 2006.

Individuals with structural brain abnormalities are more likely to experience status epilepticus. Status epilepticus is a condition of generalized convulsions in adults and older children (older than 5 years) for 5 minutes continuously or two or more discrete seizures without full recovery of consciousness.[28-30] Treatment initially includes benzodiazepines, which are often effective; if two doses of a benzodiazepine are not effective, subsequent doses are not likely to work, and phenytoin (Dilantin) or fosphenytoin (Cerebyx) is considered the next line of medication.[28] It is important to rapidly assess for and to treat underlying conditions that may have triggered the seizure or make it refractory to standard therapies, even in patients with known seizure disorders. This includes testing for hypoglycemia and electrolyte abnormalities, such as hyponatremia, as well as a focused history and physical examination looking for signs of trauma, infection, or changes in home medications. (For complete discussions of the management of adult and childhood seizures, see Chapters 102 and 175, respectively.) Intractable epilepsy affects approximately 20 to 30% of

www.ketabpezeshki.com 66485457-66963820

patients with seizures. Newer antiepileptic drugs and surgical procedures decrease seizure frequency in a significant number of patients. Even among this group, up to 10% continue to have disabling seizures. For these patients, the vagal nerve stimulator (VNS) provides hope for better seizure control.[31]

The VNS is an implantable device that looks like a pacemaker. It is implanted by a neurosurgeon just under the skin in the chest. In the small number of children who have had the VNS placed, most have had a reduction in seizure frequency of 50%.[31] How the VNS works on the brain is not known. The VNS is programmed by the neurologist with a programming wand and a laptop computer to provide baseline intermittent stimulation of the left vagus nerve. Although the VNS system delivers stimulation automatically in regular pulses all the time, a special magnet can be used to deliver extra electronic stimulation in between cycles. The patient or caregiver activates the device by placing the hand-held magnet over the device implanted in the chest.[32] Patients who can sense that they are about to experience a seizure can activate the VNS themselves by passing the magnet over the device. Out-of-hospital providers who encounter a seizing patient with the VNS should assist the caregiver with its activation or seek advice from medical control. Individuals with VNS devices should otherwise be treated like other seizing patients, with careful attention to airway, breathing, and circulation. The special magnet can also be used to stop the stimulation by holding the magnet over the device. While the magnet is held directly over the generator, the switch inside the generator remains closed and stimulation is not delivered. When the magnet is removed, the switch opens and the device is able to deliver stimulation.[33,34] Sometimes the patient may want to shut the stimulation off. Some reasons for this include when the patient is eating if the stimulation causes problems with swallowing, when the patient plans to speak or to sing in public as the stimulation can change one's voice, and if the stimulation causes discomfort.[33]

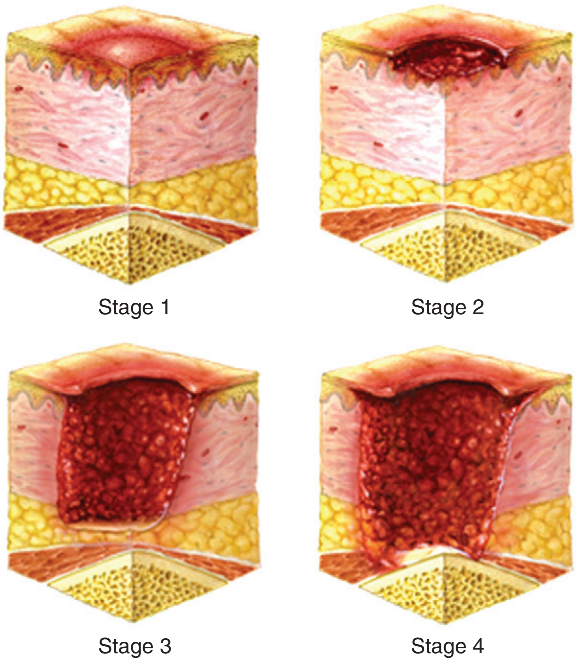

Figure 187-5. Staging of pressure ulcers. (Used with permission of the National Pressure Ulcer Advisory Panel.)

Myelomeningocele and Hydrocephalus

Myelomeningocele (or spina bifida) refers to a congenital gap in the vertebral arches. The most common types of spina bifida are spina bifida occulta, the milder form, and spina bifida associated with malformation of the spine and attachment of the sac, a condition known as myelomeningocele. The rate of spina bifida in the United States has decreased markedly since the introduction of folic acid to the diets of women of childbearing age.

Clinical presentation depends on the level of the defect. The condition results in partial or complete paralysis and loss of sensory function (not always symmetrical). In addition, the child may present with loss of bladder or bowel control, cognitive impairments, visual deficits, and seizure disorders. Bladder and bowel dysfunction is common among children with spina bifida. In such cases, there is incomplete emptying of the bladder, predisposing the child to urinary tract infections. Management of such cases requires emptying of the bladder by urinary catheterization several times a day. Hydrocephalus associated with Chiari malformation (displacement of the brainstem and part of the cerebellum downward through the skull) occurs in more than 68% of children with spina bifida.[34] Because of frequent exposure to latex products early in life, children with spina bifida should be assumed to be allergic to latex.[35,36]

Spinal Cord Disease

Spinal cord disease is a broad topic that includes traumatic injuries, damage from compressive lesions such as hematomas and abscesses, and a host of medical disorders. Some of the medical conditions include transverse myelitis, cord infarction, and multiple sclerosis. This can result in partial or complete deficits below the level of the lesion that may be unilateral or bilateral, depending on the location of the lesion. In addition to weakness, mobility may be limited by spasticity and contractures. In some situations, such as traumatic injuries, patients may know the exact level of their injury. Other diseases, such as multiple sclerosis, often have patchy and fluctuating symptoms. Regardless of the situation, it is important ask patients about their baseline level of motor and sensory function. Sensory deficits can occur internally as well as externally, so symptoms like abdominal pain and dysuria may be absent and the physical examination findings may be falsely reassuring.

Impaired sensation and strength place individuals with spinal cord disease at increased risk for pressure ulcers. The sacral region is the most commonly recognized site, although any region overlying a bone prominence is at risk for tissue injury. Examples include the occiput, elbows, heels, and posterior aspect of the pinna in the supine patient. Other risk factors for pressure ulcers include age, diabetes, chronic steroid use, tobacco exposure, and malnutrition. Pressure ulcers are categorized as stage 1 to stage 4 (Fig. 187-5). Stage 1 describes the often subtle color, temperature, and tactile changes that occur before actual ulceration. Stage 2 ulcers are shallow, with involvement limited to the epidermis and dermis. Stage 3 lesions penetrate into the subcutaneous fat, and stage 4 lesions penetrate through the deep fascia and may involve underlying muscle and bone. Prevention and early recognition are paramount as severe lesions can be refractory and often require prolonged treatment and surgical intervention. Preventive measures include frequent position changes, padded support devices, daily skin examinations, meticulous hygiene, and avoidance of temperature extremes. In some situations, hospitalization may be necessary for care of extensive wounds or treatment of superimposed infection, which may lead to bacteremia and sepsis. In one prospective cohort, pressure sores accounted for nearly 18% of hospitalizations in patients with spinal cord injury.[37] In the case of infection, blood and wound culture specimens should be obtained and antibiotics should be initiated with specific concern for skin flora.

Autonomic dysreflexia is another common problem in individuals with spinal cord injuries at or above T6. Autonomic

www.ketabpezeshki.com 66485457-66963820

dysreflexia results from inappropriate sympathetic stimulation in response to a noxious stimulus below the level of the cord lesion. The sympathetic surge leads to a subsequent parasympathetic response above the level of the lesion. Signs and symptoms include elevated blood pressure, headache, diaphoresis and flushing cephalad to the lesion, chills, anxiety, dyspnea, and palpitations. The most common cause of autonomic dysreflexia is bladder distention. Additional causes are urinary tract infections, kidney stones, bowel impaction, intra-abdominal infections, skin lesions, sexual activity, pregnancy, sexually transmitted diseases, orthopedic injuries, and deep venous thrombosis. Initial management includes rapid screening for some of the more common causes and blood pressure monitoring. Any constricting item should be removed, including clothes, watchbands, urinary catheter straps, and compression stockings. The bladder should be drained either by placing a new catheter or by flushing or replacing an existing catheter. Urine should be sent for microscopy and culture. Persistent symptoms should prompt the provider to search for other sources of infection, bowel impaction, and musculoskeletal injuries. Blood pressure should be monitored frequently in patients with severe symptoms, and short-acting antihypertensive therapy should be initiated while the patient is undergoing further evaluation. Correction of the underlying problem usually results in resolution of the presenting signs and symptoms, including elevated blood pressure. Patients may require hospitalization for treatment of the underlying cause or for persistent symptoms, regardless of cause. Complications may result from elevated blood pressures and can include ischemic events and intracranial bleeds.

Indwelling Catheters

Ventriculoperitoneal Shunts

Ventriculoperitoneal (VP) shunts are catheters that are inserted into the ventricles within the brain and then threaded under the skin from the skull to the peritoneum, where excess cerebrospinal fluid (CSF) is drained (Fig. 187-6). Less commonly the shunt may drain into the pleural space (ventriculopleural shunt) or right atrium (ventriculoatrial shunt). Hydrocephalus occurs with an obstruction somewhere in the CSF circulation system. If the obstruction is beyond the lateral ventricles, they enlarge with CSF, increasing intracranial pressure. Hydrocephalus can be seen in formerly premature infants who sustained an intracranial hemorrhage during the neonatal period and in adults with a traumatic or spontaneous subarachnoid or intraventricular hemorrhage. Both children and adults can have hydrocephalus secondary to brain tumors or other mass lesions causing obstruction of normal CSF flow. Finally, children with spina bifida (myelomeningocele) often have hydrocephalus if they have an Arnold-Chiari malformation that obstructs CSF flow.

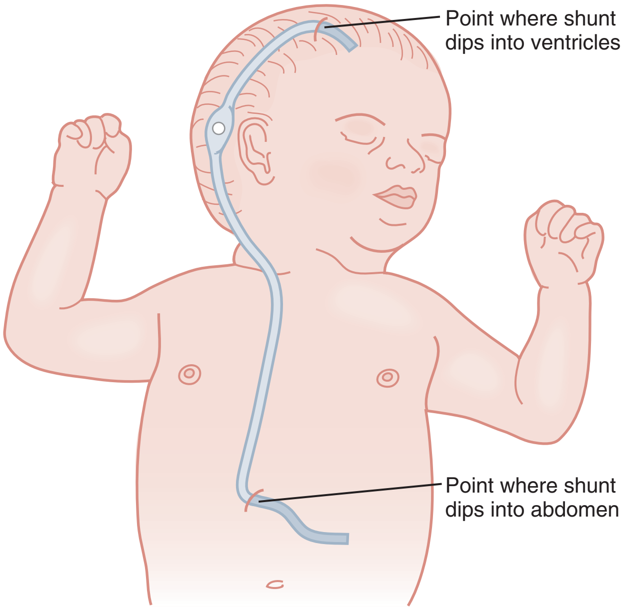

Figure 187-6. Ventriculoperitoneal shunt. (Modified from Susan Gilbert in Teaching Resource for Instructors in Prehospital Pediatrics [TRIPP]; www.cpem.org.)

A person with a VP shunt can rarely have an infection of the shunt track during the first 3 months postoperatively. Symptoms include fever, ill appearance, erythema or tenderness over the shunt site or tubing, abdominal pain and tenderness, vomiting, and altered mental status. Infection can also occur outside of the immediate postoperative setting in patients with bacteremia or primary central nervous system infections leading to seeding of the shunt. A VP shunt infection should be considered in anyone presenting with a fever; if a shunt infection is suggested clinically, CSF should be drawn from the shunt, preferably by a neurosurgeon, and sent for cell count and culture. Broad-spectrum antibiotics should be administered pending cell count and culture results; likely organisms include *Staphylococcus epidermidis, Staphylococcus aureus,* and rarely *Haemophilus influenzae*. Neurosurgeons should manage all shunt infections.[38,39]

Peritonitis is another complication of VP shunts. The tip of the shunt empties into the peritoneal cavity and as a foreign body can serve as a nidus for infection. Signs and symptoms include fever, vomiting, abdominal pain and tenderness, and abdominal distention. Management is similar to that for VP shunt infections and should include diagnostic laboratory work, broad-spectrum antibiotics, and consultation with the neurosurgeon.

The more common complication of a VP shunt is shunt obstruction or malfunction. This can occur with an increase in protein in the CSF that causes a blockage in the tubing or as a result of a mechanical disruption in the shunt tubing. This can cause a buildup of CSF in the ventricles and an increase in intracranial pressure. Signs and symptoms include headache, nausea, vomiting, irritability, altered mental status, ataxia, and change in vital signs. A bulging fontanel may also be seen in infants. Initial management should include elevation of the patient's head and management of the patient's airway, breathing, and circulation. Stable patients should have head computed tomography performed, and a neurosurgeon should be consulted as soon as possible. The definitive treatment is surgical shunt revision.[40]

Gastrostomy Tubes

Gastrostomy tubes are placed in individuals who need long-term nutritional supplementation or cannot take food by mouth. Many conditions necessitate placement of an artificial feeding tube, including severe developmental delay, coma, short bowel syndrome, swallowing difficulties and aspiration burns to the mouth and esophagus, failure to thrive, dysphagia secondary to neurologic disorders, oropharyngeal and esophageal malignant neoplasms, and chronic diseases that affect nutrition (e.g., cystic fibrosis).[41]

Gastrostomy tubes are surgically or endoscopically placed feeding catheters. These tubes include gastrostomy tubes (G tubes), jejunostomy tubes (J tubes), and percutaneous endoscopic gastrostomy tubes (PEGs or buttons). Gastric feeding is generally preferred, but a J tube may be more appropriate for patients with gastroesophageal reflux disease, delayed or impaired gastric emptying, aspiration, or pancreatitis. The tube is placed in the stomach and then passed through the junction between the stomach and jejunum, bypassing the stomach. PEGs are placed by gastroenterologists and surgeons.[42]

www.ketabpezeshki.com 66485457-66963820

There are three potential gastrostomy tube emergencies. The tube can leak gastric contents, become obstructed, or come completely out. When a patient presents with any of these problems, assessment of hydration status is important, especially in anyone who is dependent on the feeding tube for hydration and nutrition. One should inquire about prescribed medications and whether any doses were missed.[43]

If there is leaking around the catheter, management focuses on delineating and fixing the cause of the leak. Possible causes of leakage include balloon deflation, coughing, constipation, bowel obstruction, stoma dilation, and seizure. Addressing the cause may solve the problem; otherwise, consultation with the subspecialty service that manages the tube may be necessary (Table 187-4).

Sometimes a patient's G tube becomes clogged with medication or food. Obstructed tubes can be cleared with either Coca-Cola or a proteolytic enzyme solution; otherwise, they need to be replaced.[8]

G tubes that have fallen completely out of the patient need to be replaced as soon as possible so that the stoma does not constrict and make replacement difficult. Gastrostomy-jejunostomy tube placement is more challenging and is usually done under fluoroscopy by a radiologist familiar with this procedure.[42] For G tube replacement, the physician should ask when the tube was first inserted. Maturation of a tube site generally occurs within a few weeks but may be prolonged in certain populations. For tubes that are less than 3 months old, consultation with the person or service that performed the procedure is necessary because the track may not yet be fully formed and insertion by a practitioner not adept at replacement of these tubes may create a false track.

When the reinsertion procedure is performed, a similar size gastrostomy tube should be used. Families often have an extra tube with them. When a G tube is not available, a Foley catheter can be used to temporarily keep the stoma open until definitive placement can occur.[11]

Once the G tube is replaced, tube placement can be confirmed by instillation of a small amount of diatrizoate meglumine (Gastrografin) dye into the tube (15-30 mL) and obtaining two

Table 187-4 Potential Central Line Emergencies and Physician Management or Considerations

External catheter dislodgement	Apply direct pressure to the skin site. Clamp line near the exit site. Place a peripheral intravenous line to continue necessary fluids and medications. Obtain a chest radiograph to locate distal end of catheter. Consider a dye study to determine location of catheter tip. Obtain surgical consultation.
Complete catheter dislodgement	Apply direct pressure to the skin site. Place a peripheral intravenous line to continue necessary fluids and medications. Obtain surgical consultation to determine disposition.
Damaged catheter	Clamp catheter proximal to the break with a hemostat wrapped in gauze. Estimate blood loss. Observe for symptoms of air embolus. If a peripherally inserted central venous catheter line is in place, remove it. For other partially implanted lines, repair catheter if more than 2 inches of the line exit the skin.
Bleeding at catheter entry site	Apply direct pressure to the entry site. Estimate blood loss. Place a peripheral intravenous line to continue necessary fluids and medications. Obtain a chest radiograph to locate distal end of catheter. Consider a dye study to determine location of catheter tip. Obtain surgical consultation.
Internal bleeding	Apply direct pressure to the site. Observe for symptoms of hemopneumothorax. Place a peripheral intravenous line to continue necessary fluids and medications. Obtain a chest radiograph to locate distal end of catheter. Consider a dye study to determine location of catheter tip. Obtain surgical consultation.
Catheter occlusion	For problems with the withdrawal of blood, try placing the child in various positions (e.g., arms high, lying supine). Attempt to gently aspirate the clot with a 10-mL syringe half filled with normal saline placed directly onto the male Luer lock of the catheter. Consider use of a fibrinolytic agent.
Dislodgement of blood clot	Never force fluids through the catheter! Pulmonary embolism may result. Observe for tachycardia, tachypnea, hypoxemia, and chest pain. Immediately stop infusion of fluids. Clamp catheter.
Air embolus	Observe for *sudden* changes: tachypnea, chest pain, shortness of breath, or loss of consciousness. Clamp system, place child on left side in a head-down position, and give oxygen.
Fever	Consider the patient bacteremic or septicemic until it is proven otherwise. Sepsis can quickly develop in immunosuppressed children. Evaluate for source of infection. Begin broad-spectrum antibiotics. Admit to the hospital for antibiotic therapy.
Reactions from home nutrient or medication infusions	Immediately stop infusion of medications and begin infusion of normal saline. Treat signs of allergic reaction with diphenhydramine, steroids, and subcutaneous injections of 1 : 1000 epinephrine if symptoms are severe.

radiographic views (anteroposterior and cross-table lateral) to observe the tube and dye in the stomach. Confirmation of replacement of the G tube is indicated when the track is relatively new (placed within 1 month of the ED visit), when the tube is difficult to replace, or when there is any doubt that the tube is in the stomach. Patients should not be discharged home without a definitive G tube placement.

Central Venous Catheters

Central venous catheters, or central lines, are used in individuals who require frequent venous access for delivery of medications, blood products, or nutrition directly into a central vein. Common uses include chemotherapy, long-term antibiotic administration, and parenteral nutrition. Another common use is dialysis in patients with end-stage renal disease.

There are three types of catheters. Peripherally inserted central venous catheters are long catheters inserted into the cephalic vein through the antecubital fossa. The catheter is advanced into the subclavian vein. These tubes are used for temporary venous access, such as antibiotic therapy, and can be placed by nonsurgeons.

Centrally inserted central venous catheters include single- and multiple-lumen catheters and can be tunneled or nontunneled. Common insertion sites are the jugular, subclavian, and cephalic veins. Nontunneled catheters are used for temporary access and are generally limited to inpatient use. Tunneled catheters, however, are frequently used in the outpatient setting. These include the Broviac, Hickman, and Groshong catheters. These are generally placed by surgeons or radiologists. In addition to medication administration and blood draws, these catheters are frequently used in dialysis-dependent patients. They are sometimes used temporarily while waiting for more definitive access, such as a maturing arteriovenous fistula, but may also be considered permanent access for those patients with prior arteriovenous fistula complications or failures. Implanted vascular access ports (Port-A-Cath, PAS Port, and Med-A-Ports) are also common. The insertion sites and method are the same as for the tunneled central venous catheters. The distal end of the catheter consists of a reservoir that is covered with a self-healing rubber septum. This reservoir rests subcutaneously, and a special needle is needed to access this line. The advantages of the implanted vascular ports are that they need to be flushed with heparin only once a month and after each access, as opposed to daily heparin flushes, and they are hidden and so may be more acceptable to older children, for whom body image is more of an issue. They have also been shown to have lower infection rates than catheters with external ports.[44]

Complications from central venous catheters include catheter damage, catheter dislodgement, air embolus, catheter occlusion, and fever. Catheters that are damaged should be clamped proximal to the break with a hemostat. With catheters that are dislodged, the practitioner should apply direct pressure at the entry site to stop or to prevent bleeding. This is a potential life-threatening emergency. The patient should be brought to a facility that can repair or replace the catheter. Air emboli in the tubing can cause sudden onset of respiratory distress, chest pain, and altered mental status. If an embolus is suggested, the patient should be placed on his or her left side, in Trendelenburg's position, and given oxygen. Catheter occlusion may occur secondary to thrombosis. Flushing of the line with a thrombolytic is often effective in re-establishing catheter patency. Many hospitals have a nursing protocol for this procedure, which can be obtained from the pharmacy. Peripheral intravenous line placement should be considered any time a catheter is not functioning properly.

Fever is a common problem in individuals with central lines, and the central line should be considered a potential source of infection. The line is a foreign body that can act as a direct conduit for microorganisms, "which is particularly dangerous for immunocompromised patients who are at increased risk for sepsis. Treatment should include obtaining blood cultures, a complete blood count, and administration of broad-spectrum antibiotics until culture results are known. Immunocompromised patients should be admitted to the hospital for intravenous antibiotics pending blood culture results. Patients with purulence at the catheter site should also be admitted as they will likely need removal and replacement of their lines after temporary access is established. In borderline cases, consultation with the primary care physician or specialist can aid in making disposition decisions.

Bladder Catheters

Individuals with neurogenic bladder secondary to spinal cord or brainstem disease may use a variety of different approaches to bladder management. These approaches include pharmaceutical agents, intermittent catheterization, and chronic indwelling catheters. Spontaneous voiding and intermittent catheterization are associated with a lower rate of urinary tract infections; however, a chronic indwelling catheter may be necessary, depending on the location of the spinal cord lesion and the individual's level of function. Indwelling catheters may also be used in patients with altered genitourinary anatomy secondary to traumatic or postsurgical changes. Catheters may be either urethral or suprapubic in placement. Suprapubic catheters are often preferred by patients and may be associated with lower rates of infection.[45-47] Regardless of site, indwelling urinary catheters are subject to bacterial colonization. Pyuria and bacteriuria are common findings, and patients are often asymptomatic. Whereas *Escherichia coli* is still the most common pathogen, patients with spinal cord disease have higher rates of *Pseudomonas, Proteus,* and *Serratia* colonization than in the general population.[47] Candiduria is also a common finding in asymptomatic patients with long-term catheterization.[48] Determination of when to initiate antimicrobial therapy is controversial. The National Institute on Disability and Rehabilitation Research defines significant bacteriuria as $\geq 10^4$ CFU/mL for clean-void specimens, whereas any degree of bacterial growth is considered significant in patients with indwelling catheters.[49] Despite these sensitive definitions, this consensus report recommends against treatment of asymptomatic bacteriuria unless a urease-producing organism is isolated.[49] This recommendation is based on the association between urea-producing organisms, such as *Proteus,* and bladder stone formation. If a patient is febrile without another obvious source, critically ill, or symptomatic with abdominal or flank pain, vomiting, chills, or rigors, it is appropriate to treat a presumed urinary tract infection. When possible, the catheter should be replaced or temporarily removed before urine is sent for microscopy and culture. In immunocompetent patients who have minor or vague symptoms and who have appropriate follow-up care, it may be appropriate to wait for culture results before antibiotics are started.

Other catheter-related emergencies include dislodgement and obstruction. A clogged catheter should be flushed, and if it is still obstructed, it may need to be replaced. Likewise, if a catheter has been partially dislodged, the catheter balloon should be fully deflated and the catheter removed. Depending on the duration of bladder outflow obstruction and the degree of bladder distention, secondary sequelae, such as postobstructive diuresis and autonomic dysreflexia, should be considered.

KEY CONCEPTS

- Children and adults with special health care needs are usually brought to the ED by parents and caregivers who often know their child's or family member's issues well. They may have information cards or notebooks describing conditions and equipment and listing medications, or the patient may be wearing medical jewelry.
- CSHCN may be physically smaller than children of the same chronologic age, may have vital signs outside the range of normal for age, and may be developmentally delayed.
- Most CSHCN suffer the same typical diseases as their normal counterparts do. Treatment of CSHCN should begin with assessment of the child followed by assessment of medical equipment. When in doubt about the best course of action, maintain the child's airway, breathing, and circulation while seeking consultation from the child's pediatrician or surgeon.
- A common cause of respiratory distress for adults and children with tracheostomy tubes is obstruction from hardened secretions. Immediate instillation of normal saline and suctioning may relieve the obstruction. If suctioning does not relieve the obstruction or respiratory distress, the tracheostomy tube should be changed because there may be a thick mucous plug obstructing airflow through the tube. An endotracheal tube can be used as a substitute if the appropriate size of a tracheostomy tube is not available.

Chapter 188

The Combative Patient

Jason D. Heiner and Gregory P. Moore

PERSPECTIVE

Background

Combative patients are among the most difficult patients emergency physicians encounter. Often brought in against their will, they are agitated, confrontational, and nearly impossible to examine, and they may physically harm themselves or others. The emergency physician should seek to control the patient and the situation, diagnose and treat reversible causes of violence, and protect the patient and staff from harm.

Epidemiology

Violence is referred to as our nation's shameful epidemic. Injury is the leading cause of death in persons younger than 44 years, and homicide is the second leading cause of death in persons aged 15 to 24 years.[1,2] Rates of firearm violence and death from firearms are higher in the United States than in any other industrialized country.[3-5] For each death there are an estimated 19 additional injuries requiring hospitalization.[6] The high lifetime cost of treating gunshot injuries and associated disabilities is a public health issue as a large proportion of the expense is covered by U.S. taxpayers.[7-9]

The emergency department (ED) is a volatile environment because of high stress, illness, prolonged waiting times, and frequent lack of communication. The 24-hour open door policy, availability of potential hostages, and widespread accessibility of drugs and weapons compound the potential for violent behavior. Among hospital workers, the majority of assaults occur in the ED, psychiatric ward, waiting rooms, and geriatric units.[10] In a survey of 242 emergency care workers in five Midwestern hospitals, the majority reported being verbally threatened, and 51% of physicians and 67% of nurses reported being physically assaulted at least once in the past 6 months.[11] Another survey of attending physicians (n = 171) in Michigan EDs reported that 75% experienced a verbal assault and 28% a physical assault in the past 12 months; 82% were occasionally fearful of workplace violence.[12] An additional survey of 263 emergency medicine residents and attending physicians found that 78% of participants experienced a violent workplace act in the prior year and that workplace violence is experienced equally by men and women.[13] An ED census of at least 50,000 patients annually or an average waiting time of at least 2 hours is significantly associated with an increased incidence of violence.[14,15] The risk of workplace assault in the ED, however, exists across hospitals of all sizes and reflects the rate of violence in the community.[16] Despite these obvious risks, health care providers are typically not trained in the identification and management of combative patients.[13]

Patients armed with lethal weapons pose a serious threat to ED staff. The carriage of weapons in the ED population is estimated at approximately 4 to 8%.[17,18] One large urban hospital ED with a metal detector reported confiscation of an average of 5.4 weapons a day.[19] At this center, 27% of major trauma patients seen in the ED during a 14-year period were initially armed with lethal weapons (84% knives and 16% guns). The potential risk posed by concealed weapons also exists in pediatric EDs.[20] Unfortunately, prediction of weapons carriage in any particular patient is impossible.[21] Therefore, it is prudent to assume that all violent patients are armed until it is proved otherwise, especially those presenting with major trauma.

Identification of potentially violent patients is difficult; male gender, prior history of violence, and drug or ethanol abuse are the only positive predictors.[22-26] Ethnicity, diagnosis, age, marital status, and education are not reliable identifiers. A study conducted in an outpatient psychiatric setting found that the incidence of violent behavior occurring after psychiatric evaluation does not vary with the experience of the psychiatrist.[23] Actuarial prediction of patient violence in a 6-month period by use of criteria such as age, drug use, and prior history of violence is substantially more accurate than prediction of future violence by evaluating attending psychiatrists.[27] The prediction, prevention, and control of violent outbursts in the ED are difficult. Appreciation of the potential for violence, preparedness, and proper use of verbal techniques and physical or chemical restraints assist the patient while preventing injury.

PRINCIPLES OF DISEASE

Pathophysiology

The pathogenesis of violent behavior is conjectural. Potential causes include environmental, historical, interpersonal, biochemical, genetic, hormonal, neurotransmitter, and substance abuse disorders.[28-30] Psychiatric illness is also a risk factor, with schizophrenia (paranoid and nonparanoid), personality disorders, mania, and psychotic depression most frequently associated with violence.[26,29,31-33] Delusional schizophrenic patients become violent, believing that others are attempting to harm them. They may also have auditory hallucinations commanding harm to others. Antisocial and borderline personality disorder patients typically do not feel remorse for their violent actions. The patient with acute mania is unpredictably dangerous because of emotional lability, a situation in which pleasantness can quickly turn

Disclaimer: The views expressed herein are solely those of the authors and do not represent the official views of the Department of Defense or Army Medical Department.

www.ketabpezeshki.com 66485457-66963820

to aggression. Substance abuse disorders are consistently associated with violent behavior in both psychiatric and nonpsychiatric populations.[25,26,34-36] Biologically, the serotonin system controls aggression and inhibition, with diminished serotonergic function possibly disinhibiting aggression against self and others.[37-43] Generalized brain dysfunction may predispose patients to violence by disruption of the regulation of aggression, particularly in the prefrontal and temporal cortex.[28,42-44] Cerebral imaging documents both functional and structural impairments in violent criminals and antisocial patients.[42-46] Genetic and hormonal influences are also implicated in the neurobiology of aggression.[28,38,47]

MANAGEMENT

Risk Assessment

Evaluation of the combative patient begins with risk assessment and attention to safety measures. Violence often erupts after a period of mounting tension. The astute practitioner may identify verbal and nonverbal cues and subsequently have the opportunity to defuse the situation.[33,48-50] In a typical scenario, the patient first becomes angry, then resists authority, and finally becomes confrontational and violent. When physicians have a "gut feeling" that a dangerous situation may be developing, they should take appropriate precautions.[49,50] Violent behavior may also erupt without warning, especially in patients with an organic brain syndrome, so clinicians should not feel overly confident in their ability to sense impending danger.

An obviously angry ED patient should be considered potentially violent. Provocative behavior, angry demeanor, pacing, loud or pressured speech, tense posture, gripping arm rails intensely, frequently changing body position, pounding walls or throwing things, and clenched fists are all symptoms and signs of impending violence. To prevent escalation, the patient should be removed from contact with other belligerent accomplices as well as from other provocative patients. A quiet area with a window or direct observation is optimal. Because increased waiting times correlate positively with violent behavior, consider evaluating the potentially violent patient expeditiously to prevent escalation of aggression.[10,14,15] Often, the perception of preferential treatment will defuse the patient's anger.

All patients should be screened for weapons before the interview. The use of metal detection is ideal before ED entry. Patients brought to the ED by ambulance may bypass routine security booths and metal detectors.[51] The practice of undressing patients and placing them in a gown is useful both as a nonconfrontational search for weapons and for easy identification in the event of the patient's escape from the ED. Although screening and searching of patients for weapons may appear to be a violation of privacy, routine disarming of all ED patients results in an increased feeling of safety for both patients and staff.[18,52]

The ideal setting for the patient interview should emphasize privacy but not isolation.[31,50] Some EDs have seclusion rooms specifically designed for interview of potentially dangerous patients.[53] Security should be nearby and the door left open to facilitate both intervention and escape for the provider. The patient and interviewer may be seated roughly equidistant from the door, or the interviewer may sit between the patient and the door. Blocking of the door, however, poses a risk of harm to the clinician if the patient feels the urge to escape. Two exits should ideally be available, and doors should swing outward. The clinician should have unrestricted access to the door and never sit behind a desk. The room should not contain heavy or potentially dangerous objects that may be thrown. There ideally should be a mechanism to alert others of danger, such as a panic button or a code word or phrase that summons security (e.g., "I need Dr. Armstrong in here."). For personal protection, earrings, necklaces, and neckties should be removed. Personal accessories that may be used against the caregiver, such as a stethoscope or scissors, should be removed. The physician should be aware of any objects within the room or on the patient's body, such as pens, watches, or belts, that may be used as weapons.[48-50]

Verbal Management Techniques

The patient should be made as comfortable as possible, and the interviewer should adopt an honest and straightforward manner. In some cases, an agitated patient may be aware of the impulse control problem and welcome limit setting by the clinician (e.g., "I can help you with your problem, but I cannot allow you to continue threatening me or the ED staff."). The interviewer should act as an advocate for the patient. Offering a soft chair or something to eat or drink (not a hot liquid, which may be used as a weapon) may help establish trust. A significant percentage of patients relax at this point because offering food or drink appeals to their most basic human needs and builds trust. The interviewer should adopt a nonconfrontational demeanor and be an attentive and receptive listener without conveying weakness or vulnerability. The interviewer should respond verbally in a calm and soothing tone of voice. It is also important to stand at least an arm's length away and to avoid prolonged direct eye contact, approaching the patient from behind, or sudden movements.[48-50]

A key mistake in interviewing a potentially violent patient is failing to address the issue of violence directly.[23,48,49] The patient should be asked relevant questions about suicidal or homicidal ideations or plans, possession of weapons, history of violent behavior, and current use of intoxicants. Acknowledgment of the obvious (e.g., "You look angry.") may help the patient to begin sharing emotions. If the patient becomes more agitated, it is important to speak in a conciliatory manner and to offer supportive statements, such as "You obviously have a lot of will power and are good at controlling yourself," to help defuse the situation. If this is not successful, a respectful offer of medication or restraints to the patient if another health care provider is close by may prevent further escalation.

Counterproductive approaches to the combative patient include argumentation, machismo, and condescension.[48,49] These inappropriate strategies challenge patients to "prove themselves." An open threat to call security personnel also invites aggression. The clinician should be aware of her or his own reactions to the patient and avoid transference of anger. The deception of a patient (e.g., "I am sure you will be out of here in no time.") only invites violent consequences once the lie is uncovered. The unsuspecting nurse or colleague who follows the interviewer may be victimized. It is especially important not to deny or downplay threatening behavior. If verbal techniques are unsuccessful and escalation of violence occurs, the physician should leave the room and summon help.

Physical Restraints

Physical restraint should be considered when verbal techniques prove unsuccessful. The use of restraints can be humane and effective in facilitating diagnosis and treatment of the patient while preventing injury to the patient or medical staff.[48,54,55] The liability one incurs for restraining a patient against his or her will is negligible compared with the potential liability for allowing a patient to lose control and cause physical harm.[50]

Indications for emergency seclusion and restraint include the prevention of imminent harm to the patient, others, or the immediate environment and as part of an ongoing behavior treatment program.[48-50,56,57] Seclusion or restraint may be contraindicated because of the patient's clinical or medical condition. Seclusion should not be used in an unstable patient who requires close

www.ketabpezeshki.com 66485457-66963820

monitoring and should be avoided when the patient is suicidal, self-abusive, or self-mutilating or has had an intentional ingestion of drugs or poisons.[33,57] Restraints should not be applied for convenience or as a punitive response for disruptive behavior. If one is available, a colleague should document agreement with the application of restraints, mentioning the specific indications (e.g., "I restrained Mr. Smith because he told me he was going to beat me up and then took a swing at me." is preferable to "I restrained Mr. Smith because he was violent.").

The implementation of restraints should be systematic, and an ED protocol should be in place. This protocol begins when the examiner leaves the room after verbal techniques are unsuccessful. It may be helpful to consider the application of restraints as a procedure analogous to running an advanced cardiac life support code.[49] The restraint team ideally consists of at least five people, including a team leader. The leader, whether a physician, nurse, or security officer, will be the only person giving orders and should be the person with the most experience in implementing restraints. Before entering the room, the leader outlines the restraint protocol and warns of anticipated danger (e.g., the presence of objects that may be used as weapons). All team members should remove personal objects that the patient could use against them. If the patient is female, at least one member of the restraint team should be female to potentially mitigate allegations of sexual assault.

The team enters the room in force and displays a professional rather than threatening attitude. Many violent individuals calm down at this point as a large show of force protects their ego (e.g., "I would have fought back but there were too many against me."). The leader speaks to the patient in a calm and organized manner, explaining why restraints are needed and what the course of events will be (e.g., "You require a medical and psychiatric examination as well as treatment."). The patient is instructed to cooperate and to lie down to have restraints applied. Some patients are relieved at the protection to self and others afforded by restraints when they feel themselves losing control. Even if the patient suddenly appears less dangerous, however, once the decision to restrain is made, do not negotiate.

If physical force becomes necessary, one team member restrains a preassigned extremity by controlling the major joint (knee or elbow). The team leader controls the head. If the patient is armed, two mattresses can be used to charge and immobilize or sandwich the patient. Restraints are applied securely to each extremity and tied to the solid frame of the bed (not side rails, as later repositioning of side rails also repositions the patient's extremity). Leather is the optimal type of restraint because it is a physically stronger material and less constricting than typical soft restraints. For this reason, gauze should not be used. Soft restraints may help restrict extremity use in the semicooperative patient but are likely to be less effective in the truly violent patient who is continuing to struggle and attempt escape. If chest restraints are used, it is vital that adequate chest expansion for ventilation is ensured. The application of a soft Philadelphia collar to the patient's neck minimizes head banging and biting. Whenever possible, the treating physician should not actively participate in restraint application to preserve the physician-patient relationship. The restraining of patients on their sides helps prevent aspiration, although restraint supine with the head elevated is more comfortable and allows a more thorough medical examination while providing some protection against aspiration.[33,58] Once the patient is immobilized, announcing "the crisis is over" will have a calming effect on the restraint team and the patient.

After restraints are successfully applied, the patient should be monitored frequently and positions changed to prevent neurovascular sequelae such as circulatory obstruction, paresthesias, and rhabdomyolysis associated with continued combativeness. A standardized form should be completed for physically restrained patients. Documentation includes the specific indication for restraint and, ideally, colleagues' agreement that restraints are necessary.

Sudden, unexpected deaths occur in restrained patients.[59-64] Although healthy volunteers, when restrained and undergoing physical exertion, do not appear to experience clinically significant positional asphyxia,[65-67] the combative ED patient often suffers from other conditions that may predispose to increased morbidity. Patients who are cocaine or stimulant intoxicated or restrained in the prone position appear to be uniquely at risk.[59-64] Increased sympathetic tone and altered pain sensation allow exertion beyond normal physiologic limits in these patients. Sympathetic-induced vasoconstriction may impede clearance of metabolic waste products. Alteration of respiratory mechanics in an acidemic patient resulting from the position of restraint can be a contributing factor by impairment of respiratory compensation. As a general guideline, the prone restraint position should be avoided when possible and chemical sedation used when a patient continues to struggle against physical restraints.

The Joint Commission on Accreditation of Health Care Organizations has guidelines governing the use of restraint and seclusion for behavioral health patients. Educational materials and specific details about seclusion and restraint are available at www.jointcommission.org/. Several general essential elements to be provided in a restraint situation include the following:

Hospital policies and procedures guide appropriate and safe use of restraint.

The implementation of restraint or seclusion is limited to emergencies where imminent risk of harm exists to the patient or others.

Staff is trained and competent to apply restraint safely.

Staff is trained to minimize the use of restraint.

Patients in restraint are timely and regularly monitored.

Time-limited orders for restraint use are provided by licensed practitioners.

Medical records document that the use of restraint or seclusion is consistent with organizational policy.

Chemical Restraints

Chemical restraints should be considered alone or in conjunction with physical restraint in the management of an agitated or violent patient in the ED. A struggling patient who is physically restrained may have an increased risk of morbidity and mortality and may benefit from the calming effect of these medications. Chemical restraints subdue patients who may otherwise harm themselves or others and facilitates their medical evaluation and treatment. Clinical and administrative guidelines for their use are similar to those for the use of physical restraints. The use of medication to calm a patient may obscure the mental status examination and clinical diagnosis. This should be weighed, however, against the increased risk that both the patient and staff may face if such medication is withheld.

Several pharmaceutical agents can quickly achieve safe behavioral control, or "rapid tranquilization," of such a patient without oversedation. The ideal agent should be effective, safe and well tolerated, rapid in onset, titratable, and available through multiple routes of administration. In the ED, benzodiazepines and antipsychotics (also known as neuroleptics) are commonly used either alone or in combination for rapid tranquilization. The intramuscular route is often advantageous in the uncooperative and dangerous patient refusing an oral medication or an intravenous catheter. A chemical restraint should ideally be taken voluntarily by a patient as the offer of voluntary administration may restore some feeling of control and ease escalating agitation.[49,68-70] As with physical restraints, it is imperative that these patients be evaluated regularly for changes in their clinical status.

www.ketabpezeshki.com 66485457-66963820

Benzodiazepines, particularly lorazepam (Ativan) and midazolam (Versed), are often used in the ED for rapid tranquilization of an agitated or violent patient. Benzodiazepines enhance the activity of the major inhibitory neurotransmitter γ-aminobutyric acid to cause anxiolytic, anticonvulsant, and sedative effects. These agents are particularly preferred for the management of agitation caused by ethanol or sedative-hypnotic drug withdrawal as well as cocaine and sympathomimetic drug ingestions.[48,54] Although they are generally well tolerated, side effects of benzodiazepines include excessive sedation, ataxia, confusion, nausea, and respiratory depression, which may be amplified in the presence of concurrent alcohol and other depressant use.

Lorazepam is frequently preferred to other benzodiazepines because of its rapid onset of action, short half-life, route of elimination with no active metabolites, and effectiveness by oral, intramuscular (IM), or intravenous (IV) route of administration.[48,54,71] Recommended initial oral, IM, or IV doses of lorazepam range from 0.5 to 4 mg. Typical doses for chemical restraint in the ED begin at 1- to 2-mg increments intramuscularly or intravenously with upward titration as needed.[68,71] The onset of action after administration of lorazepam is generally 5 to 20 minutes if it is given intravenously or 15 to 30 minutes if it is given intramuscularly, with a duration of action of 6 to 8 hours.[54,68,72]

Midazolam is also an effective benzodiazepine for achievement of mild sedation and has a more rapid onset of action and a shorter duration of clinical effects than lorazepam. The intramuscular route is used widely to calm the agitated patient with a typical initial dose of 5 mg IM.[48,54] When it is administered intramuscularly, the medication usually takes effect in about 15 minutes with a mean duration of 2 hours.[48,54,73] In a comparison of midazolam 5 mg IM to lorazepam 2 mg IM and to the antipsychotic haloperidol 5 mg IM to sedate violent and agitated patients, all three showed similar efficacy, but midazolam demonstrated a more rapid onset of action and shorter duration of activity than the other two medications.[74] The choice of midazolam versus lorazepam should be determined by the duration of sedation desired.

Antipsychotic medications also play a prominent role in the chemical restraint of the violent ED patient. These medications include the older "typical" (or "classic") antipsychotics and the newer "atypical" antipsychotics. The precise mechanisms of action are unclear, but typical antipsychotics strongly block brain dopamine receptors, whereas the atypical antipsychotics less strongly and more specifically antagonize dopamine as well as serotonin receptors.[48,75] Both classes of antipsychotics have variable effects on other receptors, such as the adrenergic, cholinergic, and histaminic receptors.[75] The typical antipsychotics can be categorized in terms of their "potency," a description referring to the relative dosing of the medication and generally predictive of its side effect profile. The incidence of sedation, hypotension, and anticholinergic side effects is higher with the low-potency antipsychotics, whereas the incidence of extrapyramidal symptoms is greatest with the high-potency antipsychotics. Low-potency antipsychotics include chlorpromazine (Thorazine) and thioridazine (Mellaril), medium-potency antipsychotics include loxapine (Loxitane) and molindone (Moban), and high-potency antipsychotics include haloperidol (Haldol) and droperidol (Inapsine).

Of the older typical antipsychotics, the butyrophenones haloperidol and droperidol have been widely used in the emergency setting. Haloperidol is the most frequently administered antipsychotic to control the agitated patient in the ED.[48,69,70,76] It is available in oral, intramuscular, and intravenous preparations, although the commonly used intravenous route of administration is not approved by the Food and Drug Administration (FDA). Haloperidol is generally given in 2.5- to 10-mg IM doses (often 5 mg IM for the average adult), with half doses administered to the elderly and with repeated dosing every 20 to 60 minutes as needed.[48,54,71,77-79] Effects are usually seen by 30 minutes by the intramuscular route; the average patient requires fewer than three doses for the desired clinical effect.[54,71,79]

Droperidol has been commonly used at doses of 5 to 10 mg IM and 2.5 to 5 mg IV in a manner similar to haloperidol to control the agitated or combative patient.[48,80-83] Compared with haloperidol, droperidol appears to more rapidly reduce agitation at equal intramuscular dosing; it has a shorter duration of effect, more sedation, a larger incidence of orthostatic hypotension, and a lesser incidence of extrapyramidal symptoms.[78,81,84] Compared with midazolam 10 mg IM, droperidol 10 mg IM has an equally rapid onset of action and requires fewer additional doses for sedation.[85] The clinical use of droperidol decreased markedly after it was given a controversial black box warning in 2001 by the FDA for concern of QTc prolongation and torsades de pointes.[86-89]

Haloperidol is also associated with QTc prolongation and torsades de pointes.[90-93] It is prudent to use caution when these medications are administered to patients with other identified risk factors for or the known presence of existing QTc prolongation. In 2007 an FDA alert recommended electrocardiographic monitoring of patients receiving haloperidol intravenously to further minimize this risk.[94] If it is possible to obtain an electrocardiogram or to place the patient on a cardiac monitor before the administration of haloperidol, that should be done. If this is precluded by poor cooperation of the patient, it should be accomplished as soon as possible once the patient becomes more cooperative.

Common side effects of haloperidol and droperidol are sedation, orthostatic hypotension, and extrapyramidal symptoms. Extrapyramidal symptoms are thought to be due to mesolimbic dopamine receptor blockade, not dose related, and may occur immediately or days after medication administration.[78] Patients can have akathisia (extreme restlessness) and uncoordinated involuntary movements known as dystonia, including of the muscles of the mouth (buccolingual), neck (torticollis), back (opisthotonos), eyes (oculogyric crisis), and trunk (abdominopelvic). Treatment includes diphenhydramine 25 to 50 mg IV or IM or benztropine 1 to 2 mg IV or IM acutely and extended for 3 days to minimize symptom recurrence. Both haloperidol and droperidol have minimal anticholinergic properties and are often coadministered with diphenhydramine or benztropine, so they should not be used to control agitation in a patient with known anticholinergic intoxication. The use of these medications in the sympathomimetic-intoxicated patient is concerning because some antipsychotics may lower the seizure threshold. Seizure activity after administration of haloperidol or droperidol, however, appears to be a rare event, and in the animal model haloperidol is protective against seizures in cocaine intoxication and reduces mortality in amphetamine intoxication.[83,95,96]

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction estimated to occur in 0.01 to 0.02% of patients receiving antipsychotic medications.[97] Characteristic symptoms include autonomic instability, hyperthermia, lead-pipe muscle rigidity, and altered mental status. If neuroleptic malignant syndrome occurs, further antipsychotics should be withheld and supportive treatment initiated. The role for any specific pharmacotherapy is uncertain.[97]

Chemical restraint with newer atypical antipsychotics is safe and effective in the treatment of agitated and violent patients, although their role in the treatment of the ED patient is still evolving.[71,78,98] Compared with the typical antipsychotics such as haloperidol, these medications appear to provide more tranquilization than sedation, have increased efficacy on both positive and negative symptoms in the outpatient, and have fewer extrapyramidal side effects.[71,78,99,100] Their use in the ED is facilitated by intramuscular and oral dissolving tablet formulations that may assist in a smoother transition to oral dosing in those patients requiring ongoing antipsychotic therapy.[78,101-103] Atypical antipsychotics

www.ketabpezeshki.com 66485457-66963820

such as olanzapine, ziprasidone, and aripiprazole are proving useful in the ED. Although the clinical significance is uncertain, all of these atypical antipsychotics carry a black box warning associating their use with an increased risk of death in elderly patients with dementia-related psychosis.

Olanzapine (Zyprexa) is readily available in intramuscular, oral, and oral dissolving tablet formulations and has a distinct calming effect in clinical practice.[104] It has FDA-approved indications for the treatment of agitation associated with bipolar I mania and schizophrenia. Intramuscular olanzapine has an onset of action of 15 to 45 minutes after the initial administration.[54] The intramuscular form is typically administered as an initial dose of 2.5 to 10 mg with one or two subsequent doses every 2 to 4 hours for a total maximum dose of 30 mg.[105,106] Although it is generally well tolerated, side effects include sedation, mild hypotension, and anticholinergic properties that can exacerbate existing anticholinergic intoxication. Olanzapine has minimal QTc-prolonging effects and a lesser occurrence of acute dystonia and akathisia compared with haloperidol.[107-109] Compared with lorazepam 2 mg IM, olanzapine 10 mg IM demonstrates more rapid effectiveness in reducing acute agitation in patients with bipolar mania.[110] In the acutely agitated schizophrenic patient, olanzapine IM at doses of 5 mg, 7.5 mg, and 10 mg is more rapidly effective than haloperidol 7.5 mg IM.[108,109] In acute dementia-related agitation, olanzapine IM at doses of 2.5 mg and 5 mg is well tolerated and as effective as lorazepam 1 mg IM.[111]

Ziprasidone (Geodon) is FDA approved for treatment of the agitated schizophrenic and bipolar manic patient, and IM doses of 10 to 20 mg are effective in reducing acute agitation in patients with underlying psychotic disorders.[112,113] By the intramuscular route, typical dosing is 10 mg every 2 hours or 20 mg every 4 hours (not to exceed 40 mg/day) with an onset of action of 15 to 30 minutes.[69,76] Ziprasidone is generally well tolerated, although side effects such as somnolence, dizziness, and headache are not uncommon.[112,114] Ziprasidone has more QTc-prolonging effects than olanzapine, haloperidol, or risperidone and is associated with torsades in polydrug exposures.[71,115-117] This QTc-prolonging effect may be clinically insignificant in most patients, but the use of ziprasidone is not recommended in those patients with significant risk for or known QTc prolongation.[102,118-120] An observational study of ziprasidone IM in a psychiatric ED reported rapid clinical efficacy and decreased total time in restraints compared with historical controls who had received various doses of medications including haloperidol and lorazepam.[121] A randomized double-blind trial comparing IM ziprasidone 20 mg, droperidol 5 mg, and midazolam 5 mg to treat undifferentiated agitation in the ED reported a relative delay of sedation onset with ziprasidone and a more frequent need for rescue medication to achieve sedation with midazolam-treated patients.[122]

Aripiprazole (Abilify) has FDA-approved indications for the treatment of agitation associated with the schizophrenia or bipolar disorders. Recommended doses for the acutely agitated emergency patient are 5.25 to 15 mg IM (often 9.75 mg) every 2 hours as needed (to a maximum daily dose of 30 mg).[123] Compared with haloperidol IM (6.5 or 7.5 mg) in the agitated schizophrenic patient, aripiprazole 9.75 mg IM is equivalent and well tolerated without oversedation and with a lower risk of extrapyramidal symptoms.[124-126] In the treatment of the agitated bipolar patient, aripiprazole IM (9.75 and 15 mg) has comparable efficacy to lorazepam 2 mg IM and a low risk of oversedation with the 9.75-mg dose.[127]

Benzodiazepines and typical antipsychotics are commonly used in combination to chemically restrain the agitated or violent patient. Lorazepam 2 mg and haloperidol 5 mg given together are more rapidly sedating than either medication alone, have fewer adverse effects such as extrapyramidal symptoms when combined, and are compatible within the same syringe for up to 16 hours.[70,128,129] This combination, given intramuscularly or intravenously and repeated every 30 minutes as needed, is often recommended to treat the combative patient with undifferentiated agitation and no contraindications to either of these medications.[70,71,76,78,102,130] Half doses should be administered to otherwise appropriate elder patients.

Assault and Hostage Situations

Unfortunately, physical assault may occur despite appropriate precautions and interventions. When it happens, maintain a sideward posture, keeping the arms ready for self-protection. If you are faced with a punch or a kick, deflect with an arm or a leg. If choking is attempted, tuck the chin in to protect the airway and carotids. If bitten, do not pull away but rather push toward the mouth and hold the nares shut to entice opening of the mouth. If threatened with a weapon, try to appear calm and comply with demands.[50] Adopt a nonthreatening posture and avoid sudden movements. Do not attempt to reach for the weapon. Avoid argument, despair, or whining. Attempt to establish a human connection with the hostage taker.[31,131] Offering to administer aid to other ill or injured hostages allows a hostage to appear less expendable. Do not bargain or make promises, and do not lie, as the consequences could be disastrous. Reassure the hostage taker that someone authorized to hear the complaint or demand should arrive promptly.[131] If a weapon is put down, do not reach for it but rather attempt to verbally resolve the crisis while awaiting the arrival of security personnel. Legal authorities can be called on to provide a professional hostage negotiator if one is needed.

Each hospital should have a plan of action for cases of extreme violence. The plan should include prevention and safety measures, a means for rapid notification of security and police personnel, evacuation plans, medical treatment, and crisis intervention.[50,131,132] A novel approach uses a violence management team trained in the preceding techniques to provide a mechanism for dealing with aggressive patients and protecting the staff.[133]

CLINICAL FEATURES

History and Physical Examination

Once combative patients are controlled, they need to be evaluated for organic causes of their agitated behavior. Separation of functional from organic disease is a challenging task complicated by the fact that many patients with psychiatric disorders suffer from organic medical disorders that may worsen their symptoms. Patients who exhibit violent behavior that is caused or exacerbated by an organic problem may rapidly deteriorate if the medical issues are not addressed in a timely fashion. A focused history and physical examination assist the physician in differentiating functional from organic illness.

Several historical features distinguish functional (psychiatric) from organic (medical) illness. Patients older than 40 years who have a new onset of psychiatric symptoms are more likely to have an organic cause.[134,135] Also, elders are at higher risk for organic delirium from medical illness or adverse medication reactions. Patients with a history of drug or ethanol abuse may exhibit violent behavior as a manifestation of an intoxication or withdrawal syndrome. The acute onset of agitated behavior as well as behavior that waxes and wanes over time suggests an organic origin. Most psychiatric patients are alert and oriented and have a past psychiatric history. Table 188-1 lists clues to distinguish functional from organic causes of violent behavior.

The history should include psychiatric, medical, family, and social information, including suicidal ideation, medication use, and any recent changes to prescribed medications. Family and friends can often provide valuable details as the agitated patient

www.ketabpezeshki.com 66485457-66963820

may be unreliable. When they are available, they should be interviewed independently from the patient. Medical records may detail medical and psychiatric history as well as prior history of violence. Drug and ethanol use is an important part of the history as substance abuse is highly correlated with violent behavior.

The patient should be asked for permission to perform a thorough physical examination to search for an organic cause of violent behavior and to uncover any resulting injury. Restraint of the patient may be necessary to accomplish even the most rudimentary physical examination. The importance of obtaining routine vital signs including temperature and performing a thorough mental status and neurologic examination cannot be overemphasized. Patients with persistently abnormal vital signs, a clouding of consciousness, or focal neurologic findings are more likely to suffer from organic disease and require further diagnostic evaluation. A careful examination should focus on the patient's general appearance (e.g., hygiene, nourishment, tremors) and vital signs, evidence of trauma or needle tracks, characteristic odors, neurologic and mental status, and signs of a possible toxidrome (Table 188-2).[136]

DIAGNOSTIC STRATEGIES

Although some authors advocate a standardized panel of laboratory and radiographic studies for patients with psychiatric symptoms, most recommend tailoring of diagnostic studies on the basis of clinical findings.[130,134,137-141]

A rapid blood glucose determination and pulse oximetry should be obtained for all combative patients. Patients younger than 40 years with a prior psychiatric history, normal physical examination findings including vital signs, calm demeanor, normal orientation, and no physical complaints are likely to require no further diagnostic testing.[139] Additional studies that may be useful in selected patients include serum electrolyte values, blood and urine toxicology screening, serum ethanol level, thyroid function panel, cranial imaging, and electroencephalography.[29,32,50,134] A lumbar puncture may be performed if a central nervous system infection is suggested. Specific medication levels may be determined when toxic levels would affect therapy. An electrocardiogram may be useful in elders and in the setting of a suggested intentional ingestion. Patients who may have intentionally ingested a toxic substance should also have aspirin and acetaminophen level measurements as these potentially fatal ingestions may be difficult to diagnose clinically.

An additional consideration in the diagnostic workup is the concern of the psychiatrist who will ultimately evaluate the patient. Although serum ethanol and toxicology screening may not significantly influence a patient's ED treatment, the psychiatrist may use them to assess the degree to which ethanol or drug use contributes to the patient's behavioral issues.[134,142-144] Ideally, an agreement on a diagnostic strategy should be reached between the psychiatrist and emergency physician before referral. Unnecessary diagnostic testing prolongs ED length of stay and delays definitive psychiatric care.

Table 188-1 Distinguishing Organic from Functional Causes of Violent Behavior

CLINICAL FEATURE	ORGANIC: Delirium	ORGANIC: Dementia	FUNCTIONAL
Onset	Acute	Gradual	Gradual
Age at onset	Any	>50 years	<40 years
Alertness	Altered	Normal	Normal or hyperalert
Orientation	Impaired	Normal	Normal
Hallucinations	Common; can be visual, auditory, or tactile	None	Auditory in schizophrenia, otherwise uncommon
Symptom picture	Fluctuating	Stable	Stable
Abnormal vital signs	Common	Uncommon	Uncommon
Psychiatric history	No	No	Yes

DIFFERENTIAL CONSIDERATIONS

Violent behavior often occurs in association with head trauma, hypoxia, hypoglycemia, electrolyte imbalance, infections (particularly herpes encephalitis), drug intoxication or withdrawal or adverse reaction, and metabolic and endocrine derangements.[31,50] Uncommon organic causes include seizures (e.g., temporal lobe, limbic), tumors (particularly those in the limbic system), limbic encephalitis, multiple sclerosis, porphyria, Wilson's disease, Huntington's disease, sleep disorders, hyperparathyroidism, and vitamin and mineral deficiencies (e.g., folate, vitamin B_{12}, niacin, and vitamin B_6).[145] In the ED setting, drug or ethanol intoxication and withdrawal are the most common diagnoses in combative patients.[33,58] The mnemonic FIND ME (*f*unctional, *i*nfectious, *n*eurologic, *d*rugs, *m*etabolic, *e*ndocrine) helps organize a diagnostic search for the cause of violence (Box 188-1).

Medical Clearance

The emergency physician often provides "medical clearance" for the psychiatric or combative patient, although medical clearance is a misnomer and the patient is not "cleared" of all possible

Table 188-2 Vital Signs and Toxic Syndromes

TOXIN	BP	P	RR	T	PUPIL SIZE	SKIN	EXAMPLE

medical conditions on completion of the ED evaluation.[137,146] In addition, there is no standard process for the provision of what may be more accurately termed a focused medical assessment.[130]

The incidence of organic disease in patients presenting with psychiatric complaints ranges from 24 to 80%.[134,147,148] The more relevant issue for the emergency physician is to detect medical problems that are contributing to the patient's violent behavior. Misattribution of aberrant organic behavior in a patient with known psychiatric disease is a common cause of litigation.[149] Most psychiatrists rely on the emergency physician's medical assessment of the patient. Low-risk patients with functional illness can be rapidly referred for psychiatric evaluation once they are calm and cooperative with a therapeutic psychiatric interview. Patients at higher risk for an acute organic illness require further diagnostic studies.

Once the medical screening evaluation is completed, the findings should be communicated to the consulting psychiatrist. The medical record should reflect that the evaluation shows no evidence that an acute medical condition is contributing to the patient's behavior. If the cause of the patient's violent behavior is drug or ethanol intoxication, the patient should be observed until a therapeutic interview can be conducted by the psychiatrist. Alternatively, the patient may be transported to a facility where observation can occur until the effects of the intoxicants have abated.

Preparing the Emergency Department to Prevent Violence

The risk of violence in the ED should be minimized in a cost-effective manner without creating a hostile or negative environment. The prevention of violence is best accomplished by development of a system that includes ongoing staff education, adequate personnel, and a well-designed physical structure.

Security Personnel

A well-trained and responsive security force is a key element of any hospital security system. Such personnel are expensive, and their expertise is often sacrificed quickly during budget curtailments, so decisions about the type and number of guards are often made on an economic basis. The use of guns by hospital security personnel is controversial, as is allowing other armed law enforcement officers into the ED. Other devices, such as the Taser, stun gun, and mace, are suggested as less lethal alternatives to guns.

Patient Searches

Searching of patients for weapons as they enter the ED is permissible when it is performed in a nondiscriminatory manner.[131] Warning signs should be prominently displayed, perhaps reading "For the safety of patients and staff, individuals entering the ED may be screened for weapons." Almost all patients and families will cooperate with searches and may actually feel safer as a result.[52] Clear written policies about searches and disposal of contraband should be distributed to the staff and closely followed.

Alarm Systems

The goal of any alarm system is to obtain rapid appropriate response with a minimum of false alarms. A tiered alarm system is usually best. Panic buttons in each room activate a central buzzer in the department. Several designated ED personnel respond initially and then judge the level of response needed. Every ED should have at least one telephone with a direct line to police or security in case additional personnel are deemed necessary. A verbal code (e.g., "Dr. Armstrong to room 9") is also a useful adjunct.[50]

Limited Access to the Emergency Department

Control of flow into the ED can be an effective method of preventing violent acts. High-risk departments should limit access to one or two entrances, especially during the evening hours. Bulletproof glass barriers and buzzer access systems are useful as well.

Use of a Designated Room

The American College of Emergency Physicians recommends that most EDs contain at least one secure examination room with

www.ketabpezeshki.com 66485457-66963820

shatterproof ceiling lights, solid ceiling, heavy indestructible chairs, well-secured restraint bed, two doors that can be locked from the outside, and emergency distress button that can be activated unobtrusively.[131] If it is desired, this room can be set up for video monitoring by security or ED staff. One large urban county hospital with a high incidence of violent behavior in the ED is equipped with a large security force, metal detectors, bulletproof Plexiglas triage area, keypad security entry, controlled entryway into the ED, and metal bars to prohibit cars from driving into the department.[19] This hospital reported no occurrence of weapons-related violence or injury in the ED after these measures were implemented.

Prevention

The concepts of primary, secondary, and tertiary prevention of violence can be applied to the ED environment.[14] Primary prevention refers to trying to control those factors that encourage the development of frustration and aggression. Long waiting times are associated with development of violent behavior. Attempts to shorten waiting times and to make the waiting room environment as pleasant as possible may diminish previolent aggression. The presence of surveillance cameras and a visible security force also act as deterrents.

Secondary prevention of violence involves response to previolent agitation and aggression. Successful intervention involves the recognition of risk and implementation of de-escalation techniques. Staff should be trained to recognize previolent individuals who should be seen in a timely manner. The aura of preferential treatment often defuses the situation.[133] Training of staff in techniques for management of violence leads to increased staff confidence and comfort while decreasing the rate of aggressive incidents.[150,151]

Tertiary prevention refers to limitation of the actual act of violence itself once it has occurred. Physical and chemical restraints are used, and security and police intervention are often needed. Protocols for dealing with the violent patient are important to minimize risks to the patient and staff. Enhanced security measures may be indicated in an ED with substantial risk for violence.

Violence is increasingly a major public health issue, with increased focus on improving surveillance and universal preventive measures to target large populations.[152-154] Physicians are increasingly aware of their role in reducing violence, and the ED is uniquely positioned to have an impact on at-risk populations. Proposed agendas for violence prevention for emergency medicine include improvements in medical education, research, and clinical practice as well as involvement with public education and advocacy.[155,156] Resources, particularly those aimed at youth violence intervention and prevention in the medical setting, are available to assist health care providers in the ED.[154]

KEY CONCEPTS

- ED staff should be trained to recognize potentially violent individuals and to intervene with de-escalation techniques.
- The ED should have a written plan of action to deal with violence that integrates the activities of ED staff, hospital administration, security, and local authorities.
- The emergency physician should be familiar with the use of physical and chemical restraints.
- The possibility of an organic (medical) cause of aggressive behavior should be considered in all violent patients, even those with known psychiatric disease.
- ED leadership should be proactive in attempting to create an environment that is safe and supportive for both patients and staff.

CHAPTER 189

THE DIFFICULT PATIENT

Robert J. Vissers

PERSPECTIVE

Certain patients consistently arouse negative reactions in health care providers. These negative reactions may be initiated by a patient's appearance, apparent attitude, interactive style, or presenting complaint. Difficult patients can rapidly disrupt the harmony and efficiency of an emergency department (ED). Such patients are referred to with a number of pejorative terms, such as *gomer, crock,* and other even less complimentary slang terms of disdain. They may receive suboptimal medical care, impede patient flow, and adversely influence the quality of care given to other patients, thus posing a medicolegal risk. Moreover, recurrent exposure to such patients, in the absence of a well-thought-out approach to dealing with them, may lead to escalating frustration for staff, promote unprofessional behaviors, and contribute to eventual burnout.

Historically, the medical literature has largely ignored the possibility of a physician's harboring negative feelings toward any type of patient. Anger, hatred, and frustration are traditionally considered feelings that physicians should disown in favor of humor, compassion, and integrity. Although these are admirable attributes, to deny the presence of negative reactions is unrealistic. Physicians are as human as the patients they serve. Not until Freud coined the term *countertransference* were the negative reactions that patients can arouse in physicians actually recognized for their potential effect on care and used as diagnostic tools.

Good interpersonal skills are essential to the maintenance of the patient-physician relationship.[1] Although some clinicians have more natural abilities in this area than others do, the myth that these skills are intuitive and cannot be taught is erroneous.[2] Teaching of communication and relationship-building skills is now a priority of most medical schools and many primary care specialties.[3] Guidelines for teaching and evaluating interpersonal skills within emergency medicine residency programs have been developed.[2,4,5] The Accreditation Council for Graduate Medical Education identifies professionalism and interpersonal communication skills as two of the six core competencies required in the curriculum of all U.S. residency programs, including emergency medicine, prompting greater interest in research and education in these areas. Although it remains a challenge to measure the effectiveness of these initiatives, innovative curricula on professionalism and communication are being implemented in emergency medicine residencies.[6-9]

DISTINGUISHING PRINCIPLES

Difficult patients are often referred to as problem patients, disruptive medical patients, unwanted patients, and, less diplomatically, hateful patients.[10] Patients with personality disorders are commonly included in this group because of their rigid, maladaptive personality traits. Difficult patients, however, do not necessarily have personality disorders and may fall into one of several other familiar patient categories (e.g., drug seekers, hostile patients, malingerers, and ED repeaters).

There is no universally agreed on definition of the difficult patient. The difficult patient is *one who interferes with the physician's ability to establish a normal patient-physician relationship.* This impaired patient-physician relationship is often but not necessarily associated with negative feelings toward the patient.

PATHOLOGY OF THE PATIENT-PHYSICIAN RELATIONSHIP

An understanding of the difficult patient-physician relationship is hampered by a tendency to view it as a consequence of some inherent problem with the patient. Physician characteristics and the ED environment also play a role.[11-13]

Physician Factors

Impaired communication is a common problem in all forms of interpersonal relations and is often exaggerated in the medical setting. Patient satisfaction is highly correlated with patients' beliefs that clinicians listen to them and understand their requests, coupled with the perceived professionalism of the physician.[14,15] Despite this, physicians continue to focus on their own medical agenda, which may differ from patients' concerns. When confronted with patients who have difficult social situations, physicians exacerbate the problem when they refuse to deviate from their own rigid medical model.

Physicians often have preconceived notions of how patients should behave when they are ill and tend to rapidly categorize them as either the acceptable "truly sick" patient type or the "burdensome, difficult" patient type. Patients placed within the former category are excused for their symptoms, but patients in the latter category are not. Patients may also be judged as difficult when cultural differences or language barriers interfere with the development of a mutual understanding between patient and physician.[13]

Physician failure to provide sufficient and interpretable information to patients about their diagnosis, treatment, and follow-up evaluation is another area of common communication breakdown. Studies show that in 20 minutes of patient-physician interaction, only 1 minute is reserved for educating patients about the illness.[16] Personal biases and prejudices also affect patient treatment.[11,12,17] The rapid formulation of an opinion based solely on appearance is a skill that physicians rely on to quickly form a "gestalt" about a patient. This is an essential skill for an emergency

www.ketabpezeshki.com 66485457-66963820

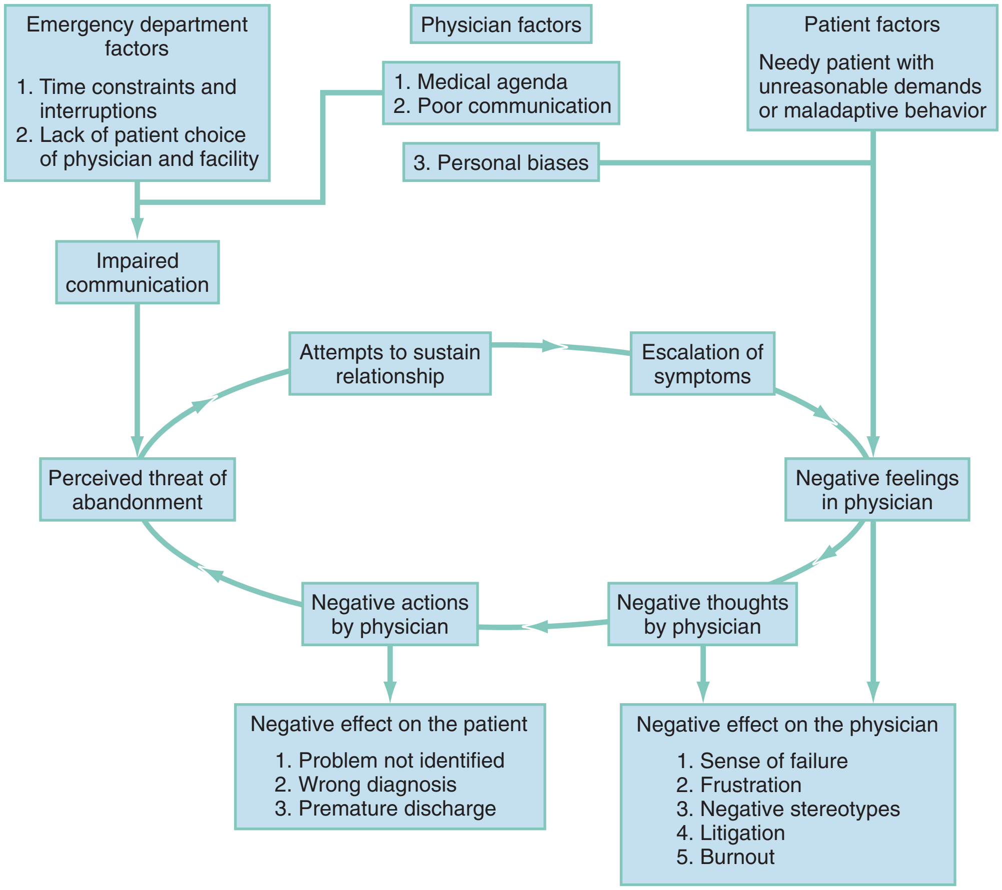

Figure 189-1. Cycle of the impaired patient-physician relationship.

physician. To assume that such preconceived notions are influential only in a positive way, however, is unrealistic.[18]

Emergency Department Factors

The ED is an environment plagued with distractions and frequent interruptions, rarely approaching the comforting atmosphere that many patients expect and deserve.[19,20] A sense of urgency and strict time constraints are often present. Patient assessments are sometimes conducted in suboptimal environments, such as hallways. The physician interaction is often perceived to be brief and punctuated by interruptions, which may imply to the patient that the physician does not care or that the evaluation is incomplete.[19-22] Patients may enter the encounter frustrated because of a lack of choice about their physicians or facilities and upset because of long waiting times, and physicians may enter the encounter biased by nursing comments or stressed by the prospect of losing control of the department while trying to deal with these particularly challenging patients.[13]

The Cycle of Impaired Patient-Physician Relationships

Difficult patients are often perceived by the physician to be making unreasonable demands (Fig. 189-1). Physicians react with negative feelings and may direct negative actions toward the patient. Patients are sensitive to these negative reactions, feel threatened with abandonment, and attempt to sustain the relationship by escalating symptoms. Physicians experience greater frustration at the maladaptive behavior of the patients, and so the cycle is perpetuated.

The consequences of this impaired relationship for the patient include failure to identify the real problems, missing of medical diagnoses, "another poor experience" with the medical establishment, and premature or inappropriate discharge.[23] The negative effect on the staff is manifested by frustration, a sense of failure and defeat, fear of litigation, and the development of unconstructive stereotypes and unrecognized prejudices, all of which may contribute to eventual professional burnout.

STRATEGIES FOR TREATMENT OF THE DIFFICULT PATIENT

This section discusses the treatment of difficult patients from three approaches: general strategies, dealing with negative reactions, and crisis intervention.

General Strategies

Box 189-1 lists several general strategies that are helpful in dealing with difficult patients.

Be Supportive

Being supportive is not always the natural response to difficult patients because of the negative feelings they arouse in the physician. Nevertheless, initiating the interaction with a clear and explicit demonstration of concern and empathy may be the single most powerful tool at one's disposal. Some physicians are concerned that seeming to be "soft" with a demanding or entitled patient may exacerbate the situation. To the contrary, expressing a respectful and empathetic concern for their problem effectively

www.ketabpezeshki.com 66485457-66963820

Box 189-1 General Strategies for Dealing with Difficult Patients

Be supportive.
Structure the interview.
Set limits.
Point out impasses.
Share your reactions.
Redirect the interview.
Take time out.
Use teamwork.
Understand the patient's agenda.

disarms many patients who are preparing for a long and arduous battle to be taken seriously. The possible news that there is no immediate solution available is more willingly received by patients who are convinced that they have been heard and believe the physician's desire to help is sincere.[24]

Connecting emotionally with the patient can take time. Initially addressing a smaller concern in a caring and respectful manner can build trust and create greater rapport and compliance. For example, a patient who seeks treatment for self-inflicted lacerations but who will not cooperate with a history aimed at assessment of suicidal risk is often more candid after the physician has rendered appropriate wound care in a nonjudgmental way.

Structure the Interview

Setting of self-imposed time limits for contact with difficult patients helps control the anxiety associated with falling behind in a busy ED. Flexibility in the structure of the assessment may be necessary. It is fair and appropriate to tell the patient of the need to excuse oneself to care for other patients. The fulfilled promise of returning to complete the next element of the assessment helps build trust and rapport.

Set Limits

It is helpful to share the ground rules of reasonable behavior with patients. For example, profane patients should be reminded that they are entitled to treatment but that their language may offend other patients. The physician may suggest that they censor their remarks or be escorted from the area.

Point Out Impasses

At times, patient expectations and physician limit setting produce an impasse. When this occurs, it may be necessary to agree to disagree. Some issues can be resolved by pointing out impasses and giving the patient a chance to help solve the problem. Impasses sometimes can be resolved if difficult issues are set aside and returned to later in the interview. This fundamental approach to negotiations is generally underused in the ED.

Share Your Reactions

Pointing out impasses may not be effective if a patient senses annoyance or frustration in the physician. It may be helpful at such times to share one's feelings explicitly with the patient while continuing treatment.

Redirect the Interview

Some patients love to talk about issues unrelated to the problem at hand. Pursuing trivial or chronic complaints should be avoided. Patients often require redirection to focus on issues that have some potential for resolution. Asking them to take a chronologic approach in discussing a specific concern may help keep them on track.

Take Time Out

Physicians occasionally feel unable to contain their frustration. One should feel comfortable retreating from the room and returning when both parties have regained their composure.

Use Teamwork

Individuals who intimidate or split the staff are much more easily treated from the outset with teamwork. This is especially important with violent patients requiring restraint when a show of strength in numbers may defuse potentially dangerous situations. A more subtle but equally important application of teamwork is in the treatment and discharge planning of patients with complex problems who require an especially well organized, multidisciplinary approach involving medical and support services in the community. On occasion, if it is available, the benefit of a "second opinion" from an emergency medicine colleague can help identify the difficult patient and allow the treating physician to regain clinical perspective.

Understand the Patient's Agenda

Sometimes physicians ask themselves, Why is this patient here?[1] It is often productive to ask the patient the same question in a nonjudgmental fashion. The patient may have an easily satisfied although unanticipated agenda. This may be as simple as needing a bus ticket to get home or reassurance that there is no immediate danger of dying of some minor disorder. When the patient's needs are not as easily met, a clear understanding of the purpose of the visit may allow the opportunity to set more realistic goals.[25]

Dealing with Negative Reactions

Although negative reactions make dealing with difficult patients an unpleasant experience, they can also provide valuable diagnostic information. Physicians should accept these reactions as understandable responses to a patient's unpleasant behavior and use them to their advantage.

Physicians typically have similar reactions to certain patient behaviors. The variations in these reactions depend on the individual physician's personality style, previous experiences, and unrecognized prejudices. Physicians should know their own reactions to specific behavioral patterns to use them as diagnostic aids.

Early recognition of these reactions may, in addition to their diagnostic value, allow the physician to analyze them as the first step in preventing failure in the therapeutic relationship.[11-13]

Negative Thoughts about the Patient

Negative thoughts about patients have the greatest potential to adversely affect patient care. Patients are often placed into such stereotyped categories as drug addict, malingerer, or crock. These labels may describe individual patients more or less accurately, but the potential exists for physicians to make inaccurate and potentially dangerous assumptions on the basis of the biases linked to these labels.

The process of assigning patients to epidemiologic categories is a normal part of clinical judgment. Certain categories are used to help define the likelihood of encountering diseases in particular populations of patients, thereby influencing decisions about investigation, treatment, and disposition. The danger in dealing with difficult patients is that this process can result in inaccurate assumptions about patients and compromise patient care.

www.ketabpezeshki.com 66485457-66963820

Inaccurate assumptions about patients based on prejudicial, stereotyped labels are called *cognitive distortions*.[12,26] The following case exemplifies the effect that cognitive distortions can have on clinical decision-making.

An injection drug user requests analgesia for severe neck pain after minor trauma. The physician labels the patient a drug seeker and assumes the complaints to be fictitious. After becoming aware of the physician's assumption, the patient becomes belligerent and aggressive. He is escorted from the ED by security. A few days later, he returns with quadriplegia resulting from a cervical epidural abscess.

The physician assumed that the patient was malingering because of past experience with injection drug users and did not consider other legitimate explanations for the patient's behavior. This phenomenon, known as all-or-none thinking, leads to the real disease being overlooked.

Negative Self-Perceptions

Self-directed negative thoughts by physicians often reflect a sense of inadequacy or despair. Some patients contribute to the problem by criticizing their care in ways that reinforce the physician's feelings of inadequacy. Unreasonable expectations of patients, coupled with their secret conviction that no one can really help, combined with the all too prevalent rescue fantasies of physicians create a potent recipe for physician frustration, which in the long term can contribute to eventual burnout.

Negative Behaviors

Physician behaviors can be the most obvious manifestations of negative feelings and thoughts. Examples include rudeness, sarcasm, and indifference toward patients. A patient may receive an incomplete clinical evaluation, and unnecessary ancillary tests may be performed as an attempt to compensate. Physical or chemical restraint use, administration of naloxone, or the performance of other procedures may be used inappropriately or punitively. Analgesics may be withheld or used sparingly. Faulty communication may result in misunderstood discharge instructions and poor compliance. Impaired patient-physician relationships may lead to a refusal of care, forcing treatment against patients' wishes or resulting in their leaving against medical advice.[27]

Although patients can suffer at the hands of physicians, the potential exists for the reverse to occur. Dissatisfied patients with incorrect diagnoses and poor follow-up instructions are prone to initiate successful malpractice suits against physicians. The physician may become the victim of patient violence.[28] Negative physician behaviors can also have an effect on the rest of the ED staff. Actions viewed by colleagues as inappropriate can compromise team morale and functioning. Physicians who are feeling angry, demoralized, and stressed may vent their frustrations on team members or consulting services, resulting in a further deterioration of the immediate situation and potential damage to long-term working relationships.

Strategies to Manage Negative Reactions

Six strategies are helpful in managing physicians' negative reactions toward patients.

Maintain Appropriate Emotional Distance

Physicians should avoid reciprocating hostile reactions offered by patients. This may be difficult to resist and is best accomplished by maintaining sufficient emotional distance to avoid taking the patient's behavior personally. This "detached concern" should be balanced with sufficient emotional investment to convey a sense of caring and empathy for the patient.[11,24]

Generate Alternatives to Negative Reactions

Instead of applying negative labels, physicians should attempt to view the patient as a victim of circumstance. Patients do not choose the social and genetic pool into which they are born. They do not choose to be abused children, to suffer from psychiatric disorders, or to experience many of the life events that lead to an ED visit. They are entitled to high-quality care, delivered with courtesy and empathy, despite their behavior.

Attempt to Understand the Patient's Behavior as a Symptom

The second step in managing negative reactions is to recognize that patients relate to the world in a particular way because of their condition, culture, and circumstances. The condition may include a variety of medical and psychiatric problems, intoxication, cognitive impairment, or personality disorders or traits. The behaviors that one finds so disturbing should be recognized as the symptoms resulting from these conditions. Cultural differences and social circumstances can result in behaviors that seem irrational or difficult if the underlying issues are not understood. In attempting to maintain a compassionate approach to a particularly troubled and troubling patient, it is sometimes helpful to imagine how difficult one would find it to *be* that patient.

Look for the Cognitive Distortion

Cognitive distortions are best identified by looking for evidence that patients or situations are being stereotyped. Physicians should be aware of the effects on clinical judgment that arbitrary inferences and all-or-none thinking have on interactions with patients.[29]

Find a Rational Response to Cognitive Distortions

The initial reaction to the elderly schizophrenic patient presenting with chest pain might be to discount the symptoms as delusional. Psychosis, however, is not protective against ischemic heart disease, and the principle of first considering the most potentially life-threatening diagnosis serves both the patient and physician well in the ED.

Place Negative Reactions in Perspective by Viewing Them in Context

The ED is a stressful work environment. An expectation exists that emergency physicians will deal with problems quickly and effectively. Patients who thwart physicians' attempts to perform accordingly may be identified as undesirable. Such patients are difficult to view objectively when one is feeling overwhelmed. The frustration resulting from dealing with such difficult situations may produce an exaggerated response to a patient's behavior. Recognizing this may help reduce the loss of objectivity that leads to problems with patient care.

Although dealing with negative reactions is not the panacea for dealing with difficult patients, it provides the foundation for restructuring of one's interactions with them in a way that will ultimately benefit the patient clinically and the physician emotionally.

Crisis Intervention

Some presenting complaints, such as "can't sleep," "nervous stomach," "anxiety," and "can't cope," are especially likely to

www.ketabpezeshki.com 66485457-66963820

produce a sense of frustration and dread among caregivers. Attempts to deal with such complaints directly often prove unfruitful, partly because the patient's seemingly exaggerated affect interferes with effective communication. These are, however, all signs of a patient presenting in crisis.[30]

Anatomy of a Crisis

A crisis occurs when a hazardous event is encountered and customary problem-solving strategies prove ineffective.[24] People experience crises of various intensities many times in their lives; common examples include the death of a loved one, the loss of a job, serious illness, and domestic violence. The usual response of an individual to such stress is to experience an inner tension that mobilizes coping skills. Different problem-solving behaviors are then tried on the basis of previous experience.

If an effective means of resolving the crisis is chosen, the person returns to a more organized state. If a resolution to the crisis is not easily found, a period of disorganization follows. During this time, the person experiences intense emotions, such as confusion, anxiety, fear, anger, and despair. It is during the state of emotionally charged disorganization that a person may seek help at the ED.

Patients in crisis will, by the nature of their complaints and behavior, fall into the category of "the difficult patient" whether or not they actually are a "difficult person." It is important to be able to apply certain techniques of crisis intervention in dealing with such patients.

Dealing with the Crisis

Recognizing the Crisis. The presenting complaint of a patient in crisis may be a description of an event, situation, emotion, or physical symptom that can be vague or specific (domestic violence, inability to cope, anxiety, unwell, headache). Patients who present with crisis-related symptoms are a heterogeneous group. At one end of the spectrum are patients who have chief complaints that describe some type of emotional suffering and who do not require a traditional "medical" workup. At the other extreme are patients who need to be reassured in absolute terms about the absence of serious disease before their anxiety is alleviated. Between these two extremes are patients who partially understand how their circumstances might be contributing to their suffering. They can accept the idea that "the effect of stress often produces these kinds of physical symptoms." Many patients, however, are justifiably unwilling to accept this explanation until they believe their medical complaint is adequately assessed. This usually requires no more than a careful history and physical examination followed by reassuring communication from the physician and the patient's perception that the complaint is taken seriously.

Some patients who are in severe crisis need to be taken through the steps of formal crisis intervention. The complex nature and considerable time required for this are often beyond the scope of practice of a busy emergency physician. The unfortunate increase in the length of stay for psychiatric patients in the ED, because of diminishing resources for these patients, may provide an opportunity for social workers, psychiatrists, or psychiatric nurse practitioners to use this technique. A recognition of the patient in crisis is critical to creating a functional patient-physician relationship, addressing the underlying illness, and beginning the process of intervention (Box 189-2).

Box 189-2 Five Basic Steps in Crisis Intervention

Recognizing the crisis
Gathering basic information
Understanding the development of the crisis
Reproducing the peak tension of the crisis
Finding the solution

Gathering Basic Information. The first step in crisis intervention, after recognition of the crisis, involves gathering general information about the patient's home environment, work situation, personal relationships, and social involvements. The purpose of basic information gathering is to place the patient and the crisis into context before exploring the crisis itself. This step is time-consuming and cannot be rushed, and it needs to be performed by providers other than the emergency physician.

Understanding the Development of the Crisis. A structured interview is performed to obtain information about the sequence of events leading up to the crisis and the nature of the crisis itself. The objective is to understand the situation while keeping the interview organized and directed so that the patient can describe events without being overwhelmed by the emotion attached to them.

Reproducing the Peak Tension of the Crisis. Once the crux of the crisis is identified, the care provider should proceed to help the patient express the intense emotions associated with the situation. Through empathetic, active listening, the person in crisis is allowed to experience the previously overwhelming emotions in a safe context. This places the care provider in a position of trust and sets the stage for problem solving.

Finding the Solution. In the final phase of crisis intervention, the physician reframes the circumstances in objective, realistic, and understandable terms for all those concerned to facilitate a solution to the problem. Possible solutions to the crisis are then suggested, with participation from the involved parties, and the best plan for resolution is implemented. It is important that this be a joint effort and that the patient have some ownership of the solution.[30]

SPECIFIC APPROACHES FOR DEALING WITH DIFFICULT PATIENTS: PUTTING IT ALL TOGETHER

The various management strategies described here can be consolidated to formulate a practical approach to dealing with difficult patients. The first step is the recognition of specific behavior types, rather than traditional diagnoses. These behavior types describe the most difficult patients seen in the ED. Patients displaying some but not all characteristics of a certain behavioral type may still be amenable to the management strategies for that type.

Behavioral Classification

Individuals with personality disorders frequently present as difficult patients. Although reliably establishing the diagnosis of a personality disorder during the typical brief ED encounter is difficult, an awareness of those personality disorders having a high prevalence in the ED helps ease communication with colleagues when the diagnosis has been previously established (Box 189-3).

An alternative to the traditional diagnostic categories for classification of difficult patients is based on four specific behavioral presentations and the negative reactions they produce.[23,31] To adapt this classification system, with more neutral terms, the behavioral categories are *dependent patients, entitled patients, intractable patients,* and *self-destructive patients*. Through recognition of the difficult patient's maladaptive behavior and identification of the physician's subsequent negative reactions, patients can be placed into one of these behavioral categories. The behavioral categories in turn suggest effective treatment strategies for each patient type (Table 189-1).

www.ketabpezeshki.com 66485457-66963820

Box 189-3 Commonly Encountered Personality Disorders

Borderline Personality Disorder

Pattern of instability of interpersonal relationships, self-image, and affect that is accompanied by marked impulsiveness beginning by early adulthood and present in a variety of contexts. It may be indicated by five or more of the following:

1. Frantic efforts to avoid real or imagined abandonment
2. A pattern of unstable and intense interpersonal relationships characterized by alternating extremes of idealization and devaluation
3. Identity disturbance: markedly and persistently unstable self-image or sense of self
4. Impulsiveness in at least two areas that are potentially self-damaging (e.g., spending, sex, substance abuse, reckless driving, binge eating)
5. Recurrent suicidal behavior, gestures, threats, or self-mutilating behavior
6. Affective instability caused by a marked reactivity of mood (e.g., intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate, intense anger or difficulty controlling anger (e.g., frequent displays of temper, constant anger, recurrent physical fights)
9. Transient, stress-related paranoid ideation or severe dissociative symptoms

Antisocial Personality Disorder

Pattern of disregard for and violation of the rights of others since the age of 15 years as indicated by three or more of the following:

1. Failure to conform to social norms with respect to lawful behaviors as indicated by repeatedly performing acts that are grounds for arrest
2. Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure
3. Impulsiveness or failure to plan ahead
4. Irritability and aggressiveness, as indicated by repeated physical fights or assaults
5. Reckless disregard for safety of self or others
6. Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behavior or honor financial obligations
7. Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another

Dependent Personality Disorder

Pattern of pervasive and excessive need to be taken care of that leads to submissive and clinging behavior and fears of separation beginning by early adulthood. It may be indicated by five or more of the following:

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
2. Needs others to assume responsibility for most major areas of his or her life
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval
4. Has difficulty self-starting projects or doing things (because of a lack of self-confidence in judgment or abilities rather than a lack of motivation or energy)
5. Goes to excessive lengths to obtain nurturing and support from others, to the point of volunteering to do things that are unpleasant
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for self
7. Urgently seeks another relationship as a source of care and support when a close relationship ends
8. Is unrealistically preoccupied with fears of being abandoned

Paranoid Personality Disorder

Pattern of distrust and suspiciousness of others, such that their motives are interpreted as malevolent, beginning in early adulthood as indicated by four or more of the following:

1. Suspects, without sufficient basis, that others are being exploitive, harmful, or deceitful
2. Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
3. Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
4. Reads hidden demeaning or threatening meanings into benign remarks or events
5. Persistently bears grudges (i.e., is unforgiving of insults, injuries, or slights)
6. Perceives attacks on character or reputation that are not apparent to others and is quick to react angrily or to counterattack
7. Has recurrent suspicions, without justification, regarding the fidelity of spouse or sexual partner

Histrionic Personality Disorder

Pattern of excessive emotionality and attention seeking beginning by early adulthood as indicated by five or more of the following:

1. Is uncomfortable in situations in which the center of attention is someone else
2. Interaction with others is often characterized by inappropriate sexually seductive or provocative behavior
3. Displays rapidly shifting and shallow expression of emotions
4. Consistently uses physical appearance to draw attention to self
5. Has style of speech that is excessively impressionistic and lacking in detail
6. Shows self-dramatization, theatricality, and exaggerated expression of emotion
7. Is suggestible (i.e., easily influenced by others or circumstances)
8. Considers relationships to be more intimate than they actually are

Narcissistic Personality Disorder

Pattern of grandiosity, need for admiration, and lack of empathy beginning by early adulthood as indicated by five or more of the following:

1. Has a grandiose sense of self-importance (e.g., exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
2. Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
3. Believes self to be "special" and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
4. Requires excessive admiration
5. Has a sense of entitlement (i.e., unreasonable expectations of especially favorable treatment or automatic compliance with their expressed expectations)
6. Is interpersonally exploitive (i.e., takes advantage of others to achieve personal ends)
7. Lacks empathy, is unwilling to recognize or identify with the feelings and needs of others
8. Is often envious of others or believes that others are envious of him or her
9. Shows arrogant, haughty behaviors or attitudes

Modified from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed. Washington, DC, American Psychiatric Association, 2000.

www.ketabpezeshki.com 66485457-66963820

Table 189-1 Management Strategies: Putting It All Together

BEHAVIORAL CLASSIFICATIONS	ASSOCIATED TRADITIONAL DIAGNOSTIC CATEGORIES	SUGGESTED MANAGEMENT STRATEGIES
Dependent Patients		
Excessive needs for attention, reassurance, analgesia	Personality disorders: dependent, histrionic, borderline	Try to view the patient's neediness as a symptom. Be supportive while setting limits on the patient's expectations.
Uses helplessness and seduction	Malingerers, chronic psychiatric patients	May need crisis intervention
Physician initially feels special, then drained and frustrated		Follow up with appropriate, consistent physician
Patient increases needs when ultimately rejected		
Entitled Patients		
Fear of loss of power causes entitled behavior	Personality disorders: paranoid, narcissistic	Be supportive of entitlement to good care while setting limits on unreasonable demands.
Uses intimidation, name dropping, hostility, and threats	Substance abusers	Allow patients to choose between reasonable treatment options.
Physician feels intimidated, angry, sometimes inadequate	VIPs	Avoid power struggles.
Potential for litigation		
Intractable Patients		
Excessive needs for attention met by having unsolvable problems with multiple visits, doctor shopping, poor compliance, and no hope for successful treatment	Personality disorders: antisocial, borderline Malingerers	Distinguish from other complicated patients, and manage appropriately.
Physician feels frustrated, angry, but fears "sharing" pessimism and missing significant illness		Beware of cognitive distortions that may obscure significant illness.
Cycle of "help me, but nothing helps"		Be supportive while setting reasonable expectations.
Self-Destructive Patients		
Disregard for own health and repeated visits for serious illness	Borderline personality disorder Substance abusers	Provide appropriate medical care.
Often overtly self-destructive, denying of illness	Chronically suicidal patients	Learn to deal with own negative and nihilistic reactions to patients.
Physician feels frustrated, helpless, angry, and guilty for wishing the patient success		Look for signs of depression and consider psychiatric referral as needed.

VIPs, very important persons.

Dependent Patients

Dependent patients see physicians as inexhaustible sources of compassion and understanding. Their initially reasonable requests rapidly escalate into repeated demands for reassurance, affection, analgesia, or other forms of attention. They are excessive in their gratitude; however, the more care they receive, the more their needs multiply. Initially, the physician may feel powerful and unique. Dependent patients give the message "You're the only doctor who cares," and the physician often believes it. As the demands escalate, the physician's patience diminishes and initial feelings of inflated self-esteem are replaced with feelings of frustration, exhaustion, and failure. This leads to a natural desire to discharge or refer these patients, along with their demands, to another unfortunate physician. The patient leaves feeling rejected and then begins the same vicious circle with the next physician. Patients with certain personality disorders (dependent, borderline, and histrionic), somatoform disorders, malingering, and chronic psychiatric disorders often fall into this behavior category.[32]

Dependent patients are best treated early in the relationship before the help-rejection cycle is fully established. Some of their earliest identifying features are the negative reactions they produce in physicians. The replacement of physicians' strong feelings of self-esteem by frustration and failure is a diagnostic clue to this type of patient. Although it is important to be supportive with such patients, it is imperative to set limits as tactfully and firmly as possible. Physicians should point out their own limited time and resources. Reasonable expectations for the patient should be established while giving assurances that one will try to help. After appropriate management, disposition should be arranged, and written discharge instructions with defined criteria for return visits to the ED should be provided. The need for follow-up visits with the appropriate primary care provider should be emphasized.

Dependent patients are especially likely to seek solutions to their problems at the ED in times of crisis. Looking for the underlying issues and structuring the interview along the lines of crisis intervention can assist in finding a satisfactory resolution to the patient's problem.

Entitled Patients

Very important persons (VIPs) are often well-informed, independent professionals who may be knowledgeable in medical matters. They spend their professional lives in a position of authority and control. The traits that make them successful in the workplace,

www.ketabpezeshki.com 66485457-66963820

however, can cause them to be demanding, fault-finding, and self-entitled patients.

Entitled patients also seem to have endless needs, but instead of helplessness or seduction, they use intimidation, hostility, and threats to attain their often unreasonable demands. Entitled patients fear being helpless and dependent on physicians. They use a shield of entitlement to protect themselves. An example is the lawyer who, in his refusal to accept his illness, roams from physician to physician demanding repeated tests and opinions while threatening to sue the previous physician who had tried to help him. Physicians experience the natural responses of disgust, anger, and antagonism when they are faced with such patients. There may be an urge to enter into a power struggle with the patient. The other common temptation is to accept the patient's terms at the price of compromising his or her care. On occasion, the physician may even experience shame at being unable to meet the patient's unrealistic demands. The maladaptive behaviors of entitled patients are commonly seen in people with paranoid and narcissistic personality disorders as well as in addicted patients and VIPs.[32]

Because the behavior of the entitled patient stems from insecurity, it is important to be supportive. While reassuring patients that they are entitled to good medical care, physicians must set limits that unreasonable demands will not be met. Prolonged debates with the patient about diagnostic and therapeutic options should be avoided. Recommendations about management options should be offered and patients left to exercise their autonomy in choosing their preferred course. At the same time, physicians must communicate their acceptance of the patients' rights to exercise this control and that their decision will not jeopardize subsequent access to appropriate care.

Intractable Patients

Intractable patients, like dependent and entitled patients, have insatiable needs for emotional support. They are, however, neither seductive nor dependent in their behaviors. They present the antithesis of entitlement; they believe nothing will help. Intractable patients desperately seek help despite the failure of all previous medical assistance. Their history is punctuated by multiple emergency visits and behaviors that are self-defeating, covert, and manipulative. These negative behaviors undermine treatment and antagonize physicians, creating feelings of anger, self-doubt, and frustration. Patients with borderline and antisocial personality disorders and malingerers often fall into this behavioral category.[32]

Malingerers are among the most difficult patients presenting to the ED. Malingering is the intentional production of false or grossly exaggerated physical or psychiatric symptoms, motivated by external incentives that are unrelated to illness. These patients may be seeking narcotics, shelter, or monetary compensation; may be attempting to avoid work or criminal prosecution; or may simply be lonely.

Malingering represents deceptive, manipulative behavior and is coded in the *Diagnostic and Statistical Manual of Mental Disorders,* 4th edition (DSM-IV), as a "problem" rather than a mental disorder.[32] This contrived behavior should be distinguished from the psychiatric illness of somatoform disorders. Somatization is the involuntary production of symptoms without the patient's awareness. Unlike malingerers, somatizers are not motivated by any conscious desire for secondary gain.[33]

Repeaters are patients who frequent the ED excessively to the point that most staff know them by name. Although chronic schizophrenics often fall into this category, this behavior can occur in any patient with poor coping skills and maladaptive responses to psychosocial stressors. The easy accessibility of the ED often makes it the only support system immediately available to chronically decompensated patients. Despite the perception that "frequent flyers" are often inappropriate in their ED use, studies demonstrate that frequent users are in poor health and require medical attention more often than less frequent users.[34,35]

Geriatric patients with multiple medical problems and those abandoned in the ED by caretakers who are no longer willing or able to meet their needs are also patient types that deserve special attention. Although these patients have problems that are often difficult to solve, the patients themselves are not necessarily difficult people.

Intractable patients elicit strong negative reactions from physicians and are sometimes identified by the feelings of futility that they produce in their caregivers. Their multiple, vague complaints that defy diagnosis and successful treatment often cause them to be labeled crocks, along with dependent patients.

Intractable patients pose a particular risk of missed diagnosis or premature discharge. Physicians should avoid the temptation to overreact with cognitive distortions and dismiss the possibility of genuine illness in the patient. Intractable patients should be distinguished from other complicated patients, evaluated for conditions that require immediate intervention, and provided appropriate management and disposition. Alternatively, there may be a tendency to inappropriately launch into extensive investigations if the behavior type is not recognized. Collateral information from previous medical records and other caregivers is valuable in providing diagnostic guidance.

Because this type of behavior stems from a need for a relationship and fear of rejection, it is important for physicians to be supportive. The belief that showing empathy only encourages maladaptive behavior is generally untrue. To the contrary, an escalation of symptoms usually follows when these patients interpret a physician's lack of concern as rejection.

Nevertheless, limits should be set regarding patients' expectations. Physicians should use this strategy while acknowledging the difficulty of the patients' problems and sharing their deep concern, and perhaps even pessimism, about the outcome of the investigations and treatment. It is helpful to make statements such as, "You know, Mr. Jones, you obviously have a very difficult problem here. You've seen lots of doctors and had lots of tests and treatments that don't seem to be helping much. There is no way, given the limited resources available in the ED at 11 o'clock on a Friday night, that we are going to be able to get to the bottom of this. What I can do is examine you and do some tests to make sure that there is no new, serious problem going on tonight. Then you will be able to follow up with your regular doctor on Monday." In this way the physician can communicate both an interest in the patient and empathy for the patient's condition while setting limits on expectations. Both the physician and patient then understand the "contract" and have a way of terminating the encounter satisfactorily.[25]

Self-Destructive Patients

Self-destructive patients are particularly difficult to treat. Unlike intractable patients, they do not seek help. Rather, they are repeatedly brought to the ED because of their neglectful and self-destructive behaviors. Their ability to deny their problems is profound and sets up the maladaptive cycle of "nothing is wrong and nothing will help." Yet their behaviors often require repeated heroic efforts to save their lives. Their chronic self-destructive behaviors may temporarily meet their immediate needs of shelter and food and perhaps, paradoxically, some of the attention they outwardly reject. This lethal cycle usually leads to a premature death. The *substance abuser,* the *violent patient,* and the *suicidal patient* are included in this category of difficult patient.[10]

It is not surprising that ED staff respond to such patients negatively, feel frustrated and helpless, and may even secretly wish

www.ketabpezeshki.com 66485457-66963820

them success in their self-destructive efforts. These are among the most difficult patients to treat. In reality, physicians can do little apart from providing appropriate care for the multiple presentations characteristic of this type of patient. The greatest obstacle for physicians may be to come to terms with their own complacency about the survival or demise of such patients. The lack of real concern about whether they live or die, or worse, actually wishing that they would die, is repugnant and produces feelings of self-recrimination. Our inability to relate to the self-destructive decisions made by these individuals contributes to our complacency about their plight. Remembering our own human weaknesses or risk-taking behaviors and viewing their seemingly incomprehensible behavior as a difference in degree rather than in kind may help us to have more empathy for them.[11] Being supportive is important. Signs of depression in the patient may indicate the need for psychiatric referral. These patients should be screened for risk of suicide and, when appropriate, held for psychiatric evaluation after medical stabilization.

SUMMARY

Dealing with difficult patients is a common problem in the ED. The impaired patient-physician relationships associated with them have multiple negative implications for both patients and physicians. Their treatment may be optimized by use of the general principles discussed in this chapter, by dealing realistically with one's own negative reactions, and by use of techniques of crisis intervention when it is appropriate. These strategies are best applied within the context of a behavioral classification that avoids pejorative terms and stereotypes, labels that differentiate them from "worthier" patients.[11] Although this approach is not a panacea for dealing with difficult patients, the framework may help physicians render appropriate care while minimizing personal frustration, medicolegal exposure, and eventual physician burnout.

One of the great challenges of medical practice is to maintain humanity when caring for these difficult and highly vulnerable individuals. By focusing on their humanity, we have the best chance of preserving our own.[11] It is easy to care for patients who generate sympathy and noble to care for those who do not.[13]

In the end, the ability to accept distressing behavior as a symptom and to treat even the most irritating individuals with compassion and kindness may be the key to surviving them. When asked how he had avoided burnout after decades in emergency medicine, one well-known patriarch of the specialty simply responded, "You've got to love the patients."[36] This is a tall order, and not meant in the literal sense. But the degree to which we can show caring and empathy, even to the unlovable, may be the key to maintaining the quality of our care, our satisfaction with the specialty, and our long-term survival in practice.

KEY CONCEPTS

- Difficult patients may elicit negative reactions in caregivers, resulting in undesirable implications for both themselves and their caregivers.
- Management of the difficult patient can be optimized by understanding the multiple factors contributing to the impaired physician-patient relationship.
- Behavioral classifications should be used instead of pejorative stereotypes in characterizing difficult behaviors.
- General and specific strategies, including understanding of our own reactions, are helpful in dealing with the impaired physician-patient relationship.
- The ability to accept difficult behaviors as symptoms and to treat even the most difficult patient with kindness is central to providing good care while avoiding personal frustration, medicolegal repercussions, and physician burnout.

CHAPTER 190

Emergency Medical Services: Overview and Ground Transport

Thomas H. Blackwell

PERSPECTIVE

Development of Emergency Medical Services

Before the advent of civilian ambulance services, the sick and injured were transported by any means available, including passerby motorists, wagons, farm machinery, delivery carts, buses, and taxicabs. Figure 190-1 depicts the early Larrey ambulance used during the Napoleonic Wars, the Rucker wagon used during the American Civil War, and a modern ambulance used today. In 1865, the Commercial Hospital in Cincinnati established the first hospital-based ambulance service. Four years later, the first city service began at New York's Bellevue Hospital.[1]

In 1965, the President's Commission on Highway Safety recommended a National Accident Response Program to decrease death and injury from highway accidents.[2] Results from a second national survey by the National Academy of Sciences–National Research Council were used to draft a white paper entitled *Accidental Death and Disability: The Neglected Disease of Modern Society*.[3] Published in 1966, this document described the hazardous conditions of emergency care provision at all levels and outlined the necessary building blocks for future maturation of emergency medical services (EMS). These national efforts were the impetus for congressional legislation that directed the U.S. Department of Transportation (DOT)–National Highway Traffic Safety Administration (NHTSA) to develop a program for improving emergency medical care.

During the mid-1960s, out-of-hospital cardiac care included field defibrillation programs in Belfast, Northern Ireland, and cardiac arrest research in several U.S. cities.[4,5] In 1969, the first National Conference on EMS convened, resulting in the development of a curriculum, certification process, and national registry for the emergency medical technician–ambulance (EMT-A). By 1972, the U.S. Department of Labor recognized the EMT as an occupational specialty.[6] Interested physicians and nurses later provided advanced educational courses and practical experiences for the EMTs, and thus began the paramedic providers.[7,8]

Additional programs prompted Congressional passage of the EMS Systems Act of 1973 (P.L. 93-154), which authorized funding that dramatically improved the development of comprehensive regional EMS delivery systems. Efforts to improve pediatric emergency care occurred in 1984 when Congress adopted the Emergency Medical Services for Children (EMS-C) initiative through the Health Services, Preventive Health Services, and Home Community Based Services Act of 1984 (P.L. 98-555).[9] An Institute of Medicine (IOM) study, released in 1994, promoted the integration of EMS-C not just into existing EMS systems but into comprehensive systems of care provision, including injury prevention, primary and definitive care, and rehabilitation services.[10]

In 1996, the NHTSA published *Emergency Medical Services Agenda for the Future,* which broadly outlined the principles required for future EMS development.[11] All components of an EMS system, both operational and clinical, were identified and discussed. This document has been used by many individuals and organizations as valuable reference material for planning, administration, and forecasting of the future of EMS delivery. More than 40 years since publishing the 1966 white paper, the IOM released a report on the status of emergency care entitled *The Future of Emergency Care in United States Health System*. The report focused on three separate yet related topics: (1) emergency care: at the breaking point, (2) emergency medical services at the crossroads, and (3) emergency care for children: growing pains.[12-14]

A major focus included the need to strengthen the integration of EMS into the entire health care system because lack of such coordination often results in patients being diverted from overcrowded to inappropriate or distant facilities. The recommendation was to ensure that the delivery of emergency medical and trauma care is organized into a coordinated, regional system such that patients receive care at the most appropriate facility on the basis of their injury or illness. Additional recommendations targeting EMS improvement included national accreditation for paramedic educational programs, adoption of a national certification system for individual state licensure, and recognition of common levels of EMS certification across the United States.

The concern for inadequate funding for EMS systems operations and disaster response was also addressed. Recommendations included development by Congress of regionally funded, multiyear demonstration projects that encourage states to identify and to test strategies for creation of seamless systems of care, workforce strengthening, evidence-based practices, and disaster preparedness. It was further recommended that an advisory committee be created to work with the Centers for Medicare and Medicaid Services to improve reimbursement and policies related to reimbursement.

Finally, a small yet significant proportion of EMS transports involve the pediatric population; thus it is often difficult for prehospital providers to maintain the knowledge and skills necessary to care for critically ill or injured children. Many plans, including disaster preparedness, often neglect children. As such, the IOM report recommended several items, the most important of which is that the care of children be integrated into the overall EMS system and not separated from that of adults, with pediatric emergency care competencies being defined and training enhanced to maintain those competencies. Because it is difficult to ascertain whether systems have targeted the pediatric population, the IOM

www.ketabpezeshki.com 66485457-66963820

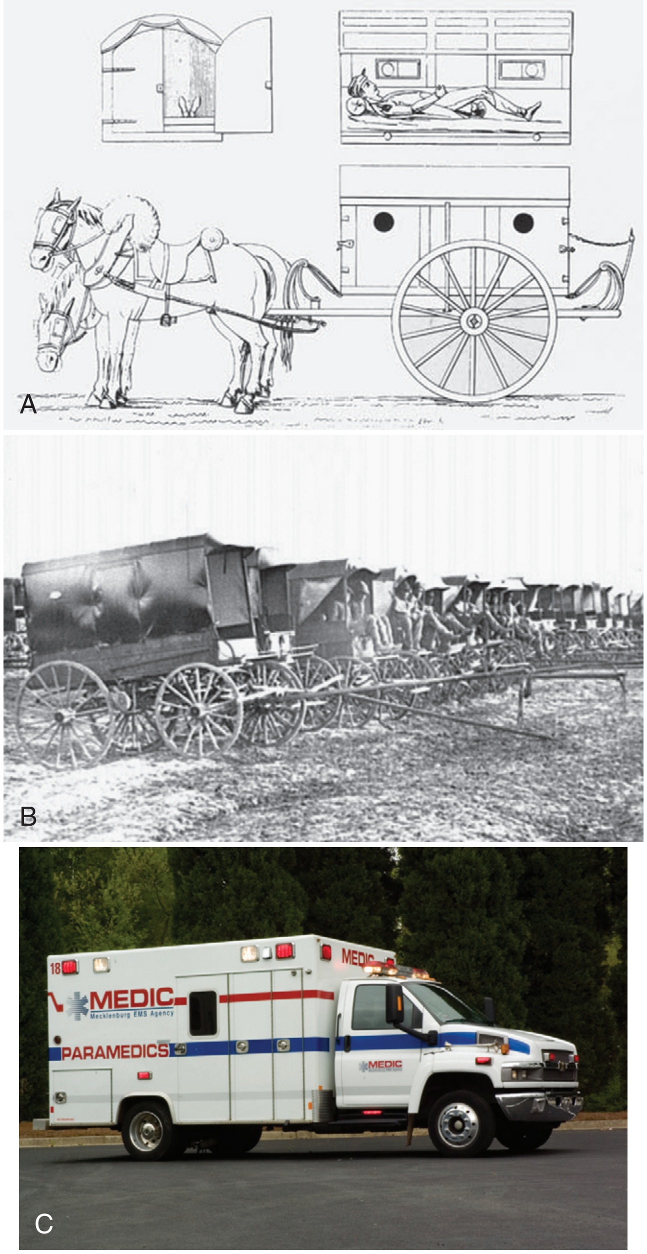

Figure 190-1. Larrey's flying ambulance (**A**), Letterman's Rucker wagon (**B**), and the modern ambulance used today (**C**). (**A** courtesy the National Library of Medicine, History of Medicine Division. **B** courtesy the Library of Congress, Prints and Photographs Division, LC-88171-2585 DLC. **C** courtesy Monroe Hicks, Mecklenburg EMS Agency, Charlotte, North Carolina.)

further recommended that a pediatric coordinator be included in all EMS systems to advocate for ensuring that equipment, medications, training, and protocols are appropriate for children.

Each of the three IOM reports supported the development by the federal government of national standards for emergency care performance indicators and evaluation and protocols for triage, treatment, and transport of patients. To accomplish this objective, a lead federal agency should be identified. Debate exists as to whether EMS at a national level should remain under the NHTSA or reside in other applicable agencies. Regardless, the parent organization should ensure that research is supported to improve the knowledge base and evidence for the practice of out-of-hospital medical care.

Emergency Medical Service Systems

Multiple EMS system designs exist, all predicated on the type of community served. Whereas this is a local decision, all states incorporate an administrative office that governs or oversees the provision of EMS activities. Typically the role is not to direct any individual service but to assist in planning, licensing services, and establishing or enforcing the scope and standards for practice. Other functions may include training, examining, certifying, and recertifying providers; record keeping; data collection; and auditing or investigating programs. A description of systems for the 200 most populous cities in the United States is periodically published in the *Journal of Emergency Medical Services.*[15] For simplicity, the following categorization of systems is used: private and public agencies; basic life support (BLS) and advanced life support (ALS) services; and single-tiered, multitiered, and first responder systems.

Private and Public Agencies

Where local government has not assumed primary responsibility for EMS services, communities may depend on private providers. Financial responsibility varies but usually depends on federal reimbursement (Medicare or Medicaid) and user fees. A local government subsidy may or may not supplement the operation. If multiple providers are serving one jurisdiction, calls may be allocated by rotation or specified zone coverage. Dispatching varies by the system but may be by the provider or by a central agency. Medical direction is often provided by a contracted physician or physician oversight board.

Hospital-based EMS systems are few in number and may be managed by a single hospital or hospital corporation. Not all hospital-based EMS programs are considered private, in that the hospital may be a division under local or state government or operating under a public authority. As in private models, financial responsibility is usually in the form of user fees, with or without additional subsidy. Dispatching may be provided by a local public safety agency that may also be responsible for police and fire communications. An emergency physician from a sponsor or base hospital typically provides medical direction for these systems.

A public utility model is a hybrid between private and public design that allows local government to contract with a private or public provider. The successful bidder for service becomes a contracted entity that agrees to provide the specified services (ALS, BLS, or both) to the catchment area and, depending on the arrangement, may bill the patient directly or receive uniform reimbursement. Depending on local structure and interagency agreement, dispatching may be performed by an existing public safety organization or by the parent company. Medical direction is usually a specified individual subject to contractual terms.

When government officials were faced with planning and establishment of EMS systems during the early maturation periods, many decided that the fire department was the logical choice to incorporate EMS. Fire stations were strategically located throughout the community, and personnel were already used to providing emergency response. Firefighters could be cross-trained as a firefighter-paramedic or dedicated to either fire or EMS function with the opportunity for transfer. Public EMS systems that were not incorporated into fire departments evolved into their own separate entity, referred to as a municipal third-service system. Such agencies are operated by local municipalities and are endorsed and supported by local government. Many cities have been successful in combining police, fire, and EMS under a global public safety agency, with all department heads or chiefs reporting to one manager or administrator. Financially, public EMS systems may be supported by a tax base, which may or may not be supplemented by user fees. Regardless of design, medical oversight for a

www.ketabpezeshki.com 66485457-66963820

municipal EMS system may be provided by a physician appointed and contracted by a local hospital, an advisory council, or a medical oversight board.

Basic Life Support and Advanced Life Support Service

BLS describes the provision of emergency care without the use of advanced therapeutic interventions. Skills include airway management (oral and nasal airways, bag-mask ventilation), cardiopulmonary resuscitation (CPR), hemorrhage control, fracture and spine immobilization, and childbirth assistance. Defibrillation with an automated external defibrillator (AED) is often included by many BLS systems. Services are provided by certified or medical first responders or emergency medical technicians (EMTs) certified at the basic level (EMT-B).

BLS systems may be associated with poor survival rates from out-of-hospital cardiac arrest, especially those not incorporating AED technology.[16] Alternatively, there is debate on the effectiveness of ALS for medical and traumatic emergencies.[17] Despite this evidence, few urban communities across the United States operate solely at the BLS level. Many rural and some suburban EMS services rely on volunteers who may not wish to become advanced-level providers. Because these services may have low call volumes, it becomes more difficult for personnel to maintain advanced skills and a proficient knowledge base. Also, such communities may not have access to medical supervision or hospital sponsorship for ALS care.[18]

Systems categorized as ALS offer a more comprehensive level of service by highly educated providers, usually certified at the intermediate or paramedic level (EMT-I or EMT-P, respectively) or equivalent levels, depending on individual state certifications. Provider skills include advanced airway interventions, intravenous line placement, medication administration, cardiac monitoring and manual defibrillation, and certain invasive procedures. Most EMS systems in urban cities operate at the ALS level of care.

The number of EMT-Ps in any jurisdiction has come under scrutiny, in that cities with more paramedics per capita tend to have lower survival rates.[19] Although this may seem implausible, one explanation might be that the number of patient encounters per paramedic decreases and the sharpness of skills degrades when that community is saturated with paramedics.

Single-Tiered, Multitiered, and First Responder Systems

In a single-tiered system, every response regardless of the call type receives the same level of personnel expertise and equipment allocation (all BLS or ALS). Multiple-tiered systems use a combination of ALS and BLS levels, depending on the nature of the call. Differences in cost and effectiveness between a mixed ALS-BLS service and an all-ALS service have been debated. A single-tiered ALS response may prove to be cost-effective in specific locales, ensures the capability of providing a consistent advanced level of care to all patients regardless of illness or injury severity, and obviates the potential for undertriage or overtriage by 9-1-1 telecommunicators. Alternatively, a multitiered system may meet the needs of individual communities or agency infrastructure. This design often meets with employee satisfaction and has the potential to preserve ALS resources for higher priority calls in that BLS transport of nonurgent patients allows ALS ambulances to be available for potential critical responses.

Regardless of single- or multiple-tier design, EMS systems usually include first responder services as part of their structure. The first responder, usually a police officer or firefighter, is the nontransport BLS or ALS provider who responds to the scene of an emergency to provide initial care before definitive medical care and transportation assets arrive. The first responder quickly assesses the situation and patients, determines whether additional resources are required, initiates patient care, and provides advance information to responding personnel.

The design of an EMS system is targeted toward providing quality patient care in the briefest time after unexpected injury or illness. A desirable and cost-effective design might include BLS nontransport first responders with short response times (average 2-4 minutes), having the capability of providing early defibrillation and airway support, coupled with ensuring ALS care and transport services.[20]

Levels of Provider and Scope of Practice

At the federal level, the NHTSA is responsible for development of the education standards and scope of practice for the different certification levels. The National EMS Education Agenda[21] and the National EMS Scope of Practice Model[22] now define the curriculum, education content, and core competencies for each level of provider. Individual state legislation is responsible for provider levels recognized, initial and continuing medical education requirements at each level, testing, and time intervals for course completion and recertification. The following sections outline the new suggested levels of provider and incorporated skills. Suggested hours of training are listed in Table 190-1.

Emergency Medical Responder

The emergency medical responder, formerly referred to as first responder, is typically the first to arrive on the scene of an incident. Initial scene and patient assessment along with limited lifesaving interventions is the primary function. Along with CPR and basic airway management skills, the emergency medical responder should be able to control hemorrhage and initiate spinal immobilization.

The four elements referred to as the chain of survival by the American Heart Association, which decrease mortality from out-of-hospital cardiac arrest, are early access to care, CPR, defibrillation, and advanced airway management and medications.[23] Because early defibrillation may improve the odds of survival of out-of-hospital cardiac arrest, the use of an AED should be a mandatory procedure for the emergency medical responder.[24]

Emergency Medical Technician

The EMT, formerly referred to as the EMT-Basic, is the minimum level required to staff a BLS ambulance and is commonly used for nonemergency and convalescent transport services. In addition to the skills of the first responder, the EMT is also involved with triage, more detailed patient assessment, and transportation. Like first responders, EMTs should have the capability of providing early defibrillation.

In 1995, the NHTSA released the revised EMT curriculum to include 46 lessons, each with cognitive, effective, and psychomotor objectives.[25] Many states expanded the course to include more skills, such as AED use, epinephrine autoinjections, albuterol administration by hand-held nebulizer or metered-dose inhaler, and use of adjunctive airway devices such as the extraglottic airway.

Advanced Emergency Medical Technician

The advanced emergency medical technician (AEMT), formerly referred to as the EMT-Intermediate, was established to allow a more comprehensive approach to care when paramedic services are unavailable or unobtainable. Many states recognize the AEMT certification, but others designate alternative but comparable

Table 190-1 Emergency Medical Services Provider Level Training and Skills

PROVIDER LEVEL	DOT RECOMMENDED HOURS OF TRAINING	SKILL SET
Emergency medical responder	Initial: 48-60 didactic and laboratory hours	Initial scene and patient assessment and stabilization Basic airway skills CPR Control hemorrhage Spinal immobilization
EMT	Initial: 150-190 hours that include didactic, laboratory, clinical, and field experience	First responder skills plus: Triage and detailed patient assessment AED May assist in some systems: use of epinephrine autoinjectors for anaphylaxis; albuterol for wheezing
Advanced EMT	Initial: 150-250 hours that include didactic, laboratory, clinical, and field experience	EMT-Basic skills plus: Endotracheal intubation Manual defibrillation Intravenous line placement Limited pharmacologic treatments May assist in some systems: laryngeal mask airway
EMT-Paramedic	Initial: Typical range of 1000-1300 hours as suggested by the Commission on Accreditation of Allied Health Education Programs	EMT-Intermediate skills plus: Cardiac rhythm recognition Expanded pharmacologic treatments Needle decompression of a tension pneumothorax Needle or surgical cricothyrotomy Transthoracic cardiac pacing

AED, automated external defibrillator; *CPR,* cardiopulmonary resuscitation; *DOT,* Department of Transportation; *EMT,* emergency medical technician.

levels, depending on specific skills and procedures. This level is useful for rural systems because it provides some ALS care for less cost and educational time expended. The scope of practice for the AEMT varies across the United States. Most systems allow the AEMT to establish an intravenous line, to manually defibrillate, and to administer limited medications.

Emergency Medical Technician–Paramedic

The EMT-P is the most advanced provider. Paramedics have the capability to address most prehospital emergencies. The scope of practice includes a wide variety of therapeutics and procedures including cardiac rhythm recognition, expanded pharmacologic treatments, and advanced airway interventions. Other important invasive procedures include needle decompression of a tension pneumothorax, needle or surgical cricothyrotomy, and transthoracic cardiac pacing.

The initial training course for the EMT-P includes didactic, clinical, and field education. All course content focuses on technical and professional competencies. Additional modules are included that allow programs to incorporate an expanded scope of practice.[26] With the expansion of EMS technology and management career options, many paramedic educational programs have advanced from 1-year certificate curriculums to 2-year associate or 4-year baccalaureate degrees. The National EMS Education Standards document recommends that all paramedic education programs be accredited in the future by the Commission on Accreditation of Allied Health Education Programs.

Future

To complement many of the educational issues addressed in the EMS Agenda for the Future document and at the request of the National Association of State EMS Officials (NASEMSO), the NHTSA along with the Health Resources and Services Administration under the Department of Health and Human Services published the *Emergency Medical Services Education Agenda for the Future: A Systems Approach* in 2000.[27] This document sets forth the processes required to improve EMS education delivery similar to what is realized with other allied health care professions, provides a means of ensuring more instructor flexibility and EMS adaptation to community needs and resources, and moves toward standardization of all levels of certification across the United States. From this document, multiple activities have been completed and published, including the National EMS Core Content, a National EMS Scope of Practice Model of minimum competencies, and the 2009 National EMS Education Standards, which would ultimately replace the current National Standard Curricula for each level of provider. The NASEMSO has been collaborating with multiple EMS stakeholders and the federal partner organizations to assist states in implementing this agenda. The National Registry of Emergency Medical Technicians is in the process of revising their examination, with a new paramedic examination being finalized by January 2013. Future goals include the establishment of a national EMS certification program, consistent levels of provider that build off of each advancing level (emergency medical responder, emergency medical technician, advanced emergency medical technician, and paramedic), the requirement for educational programs to be nationally accredited, and the limitation of examinations only to those graduates who completed these accredited programs.

Material Resources

Before the mid-1960s, few if any regulations governed system design, operations, and equipment. As EMS development progressed, guidelines for emergency vehicle specifications were adopted by the DOT and equipment lists were proposed. Today, collaborative efforts from multiple professional medical colleges and organizations continue to publish documents that recommend design, equipment, and medications for ambulances.[28]

Medications

During the 1980s, many believed that prehospital drug administration was unjustified and simply delayed hospital transport.[29,30] Moreover, although there was a profound paucity of outcomes-based research into the use of various medications and practices

www.ketabpezeshki.com 66485457-66963820

in the prehospital environment, this has been improved in recent years.[31] There is significant evidence for early defibrillation and certain advanced cardiac life support medications, which are carried by most ALS services.[24,32] The wide variety of alternative medications is less uniform. This includes respiratory and anaphylaxis medications, preparations for altered mental status, analgesics, and antiemetics. Medications are traditionally administered in the field by the parenteral route, but the intranasal route is becoming popular for certain preparations. The beneficial aspects are that absorption is rapid with an onset of action similar to that of parenteral administration. Medications that are commonly administered intranasally are naloxone for narcotic overdose, midazolam for pediatric seizure, and fentanyl for pain control.[33,34]

Equipment

Basic ambulance equipment should include items necessary for emergency procedures (i.e., airway support, hemorrhage control, fracture and spine immobilization, childbirth), personal protection, patient movement, and basic rescue procedures. Additional patient care equipment is predicated on the level of provision outlined by the system design. Many ALS systems have adopted the equipment necessary for the acquisition of prehospital 12-lead electrocardiograms to provide earlier diagnosis of acute myocardial infarction. This information often guides destination protocols to deliver these patients directly to acute care facilities that incorporate 24-hour cardiac catheterization laboratories with staff to facilitate emergent percutaneous coronary interventions.

Ambulances

Three basic ambulance vehicle designs are recognized by the DOT: type I, type II, and type III. Both type I and type III ambulances incorporate a modular patient compartment mounted on a conventional truck and van chassis, respectively. The type II vehicle is a standard van. The larger medium-duty vehicle, mounted on a business-class chassis, has become popular in recent years. This configuration requires less periodic maintenance and offers extended service time. Each ambulance manufacturer promotes various interior cabinetry and all include sufficient lighting, outlets for 110-volt equipment, suction, oxygen systems, and external audible and visual warning devices. The six-pointed blue star, or Star of Life, surrounding the staff of Aesculapius is recognized worldwide as the standard symbol for EMS.[35]

Communications

Integral to out-of-hospital care systems, EMS communications involve multiple components, all interlinked to support expedient patient care. Effective communication systems include public information and education programs regarding general access to care, technology to ensure simplified access, means of call prioritization and management of available resources, protocols for providing emergency patient care instructions before EMS arrival, ability to communicate with allied agency and hospital personnel, educational opportunities for telecommunicators, and quality improvement processes.

Access

Since 1973, the 9-1-1 universal emergency access telephone number has been adopted by many communities throughout the United States. Basic 9-1-1 service simply connects a caller to a central communications center or public safety answering point (PSAP). Most primary PSAPs are under the domain of law enforcement. Although many of these handle all public service (police, fire, EMS) calls, many larger cities have secondary PSAPs for fire and EMS. Enhanced 9-1-1 provides additional information by immediately displaying the caller's telephone number and address.

Emergency Medical Dispatch

Dispatching encompasses multiple elements that assist patients in receiving expeditious medical care.[36] There are several recognized programs with varying sensitivities and specificities that assist call-takers in identifying a patient's acuity level on the basis of the caller's information.[37,38]

The emergency medical dispatcher (EMD) is responsible for ascertaining the primary medical condition and severity. Communication centers that model their dispatch response protocols on priority use a finite list of common chief complaints, each having associated predetermined questions. Answers to these questions ultimately dictate a predefined response mode. Depending on the response assigned and system configuration, an ambulance (BLS or ALS) and possibly a first responder resource is dispatched to respond in an emergency or nonemergency mode. When critical conditions are identified, the EMD may proceed to give specific prearrival instructions to assist the caller in providing critical interventions before EMS arrival. These include procedures such as opening and clearing an airway, performing CPR, controlling hemorrhage, and assisting with childbirth. Such assistance dramatically narrows the response time interval for receiving emergency medical care.

Systems Status Management

Depending on system size, population served, and resources available, systems status management has proved beneficial for many services. On the basis of historical data, high-performance or peak-demand periods of the day coupled to service areas or call location can be identified so that coverage plans or posting assignments may be instituted. Such mechanisms place ambulances at predetermined locations where potential calls are likely to occur. Response vehicles may be equipped with an automatic vehicle locator that functions as a telemetry unit or a global positioning satellite system that provides a site interface with the computer-aided dispatch system. This site information is helpful in the staging or redeployment of vehicles during periods of high call volume or when resources are limited.

Field Communications

At the scene or during transport, EMTs usually have the capability of communicating with hospital staff. A consultative patient report may be given to receive medication or intervention orders or simply for arrival notification. Additional information resources may include cardiac telemetry or transmission of a 12-lead electrocardiogram. EMS providers should also have the capability of communicating with all allied public safety agencies for mutual aid purposes, mass casualty situations, or disaster responses. If air medical services are available, EMS and fire personnel must have the capability of communicating with the helicopter pilot and crew members. Scene personnel must relay landing zone information and potential hazards to the pilot and should provide a preliminary patient report to the medical crew.

OVERSIGHT

Federal

Various federal agencies participate in the oversight of EMS development and refinement. Specifically, the lead agency in the federal government is the EMS Division of NHTSA under the DOT. In 2007, the National EMS Advisory Council was formed to provide

www.ketabpezeshki.com 66485457-66963820

advice and recommendations from consumers, advocates, and stakeholders regarding EMS to the NHTSA. Additional federal support comes from EMS-C under the Maternal and Child Health Bureau, Department of Health and Human Services. In an effort to better coordinate federal agencies involved with state, local, tribal, or regional EMS, Congress formed the Federal Interagency Committee on EMS in 2005. The purpose of this organization is to simplify the processes and efforts by which federal agencies support EMS by identifying state and local EMS needs and recommending the addition, expansion, or improvement of programs. Although it is not regulatory, the National Association of EMS Physicians is an international organization of physicians and prehospital professionals interested in promoting research, innovation, and excellence in prehospital care delivery.

State

Each state incorporates a governmental agency that oversees EMS. Duties typically include enforcement, regulation, and implementation of EMS rules adopted by the state and possibly a medical board, licensing services, and certifying providers. The NASEMSO assists in developing policy, providing insight, and ensuring leadership and resources for EMS development at the state, regional, and local levels.

Local

EMS Medical Director

An EMS medical director is a physician with specialized interest and knowledge of patient care activities unique to the out-of-hospital environment. Medical oversight must extend from the communications center through all components of field care. Typically, a contractual arrangement for services provides the physician with administrative authority to implement patient care protocols, to interact with all aspects of the system, and to remove a provider from practice if medical care or behavior is substandard. Published guidelines describing the activities and performance of an EMS medical director have been prepared by the American College of Emergency Physicians, National Association of EMS Physicians, NHTSA, and Health Resources and Services Administration.[39-41]

Medical direction consists of off-line (indirect) and on-line (direct) control. Off-line medical control includes protocol development, personnel education, prospective and retrospective patient care review, and other quality improvement processes. Direct medical control concerns real-time interaction between a physician or designee and the field provider.

Indirect Medical Control

Medical accountability for patient care activities is the basis for indirect medical control and functions either before a patient is encountered (prospective) or after hospital transport has occurred (retrospective). Patient care guidelines and protocol development for EMTs and EMDs, continuing medical education, medical-legal policies, and quality and performance improvement processes are important elements.

Perhaps the most important duty of the medical director is to develop patient care protocols. Protocols serve as pre-established practice guidelines that define the standard of care for most illnesses or injuries encountered in the out-of-hospital setting. Operational issues, such as hospital designation and destination policies, termination of resuscitation, and patient transport refusal, may be included. Depending on state regulations, protocols may include standing orders for particular clinical situations in which EMTs may perform certain procedures or administer medications for predefined patient conditions before communication with hospital personnel. Protocol development should be driven by system resources and patient needs and should include guidelines for triage and care of specific populations of patients, including trauma patients, newborns, and children.

Regardless of local communication protocols, out-of-hospital providers should always be able to discuss a case with a physician for clarification or guidance when clinical questions or controversial situations arise. Furthermore, hospital notification is important when critical patients are being transported.

Medical directors should be familiar with and actively involved in local or regional educational programs for initial and continuing education courses for all levels of EMT certification. Course curriculum development and administration, evaluation, and revision processes should be understood. Systems that incorporate their own educational programs allow modifications that reflect intrinsic needs of the system and the providers.

Field personnel and telecommunicators should be given regularly scheduled courses that improve competency in knowledge and skills. Instructional formats and resources to accomplish educational objectives may include didactic classroom lectures, skill laboratories, direct field observation, and distance learning models for self-paced opportunities. Standardized core content is important for maintenance of consistency and quality of care.

Once patient care protocols are developed and implemented, there must be mechanisms, such as retrospective patient care report review or direct field observation, for evaluation of individual and system performance and patient outcome. Deviations from specific protocols may reflect problems with individual EMTs, medical control personnel, or the protocol itself, each requiring education and re-evaluation. Deficiencies, both operational and clinical, should be identified for appropriate remediation to occur, which may be in the form of counseling, educational instruction, or revisions of system design or patient care protocols.[42] Competency, knowledge retention, and skill performance are measurable parameters. Time standards (e.g., out-of-chute time [time from ambulance notification to deployment], response time, and scene time) are equally important measures.[43-46]

Direct Medical Control

Direct medical control is the concurrent direction of EMTs providing patient care. This may be in the form of radio or telephone communications or by direct scene observation and may be considered centralized or decentralized. In a centralized system, a selected hospital is designated the lead facility (base station hospital, resource hospital, or sponsor hospital) and is responsible for providing all direct medical control orders and notification regardless of the receiving facility. In a decentralized system, each hospital functions as a base station, providing direction to EMTs transporting patients to its facility.

Personnel responsible for direct medical control must be knowledgeable about the entire EMS system, receiving facilities, protocols, medication formulary and equipment, administrative and operational issues, and medical-legal implications for certain presenting situations. Systems whose protocols include standing orders may require direct communication only for specific reasons. Thus, whereas these medical and administrative protocols may guide EMTs through most circumstances, medical control consultation may assist with medical-legal issues, situational problems at the scene, patient nontransport, or a multitude of potential ethical dilemmas that may be encountered. Nevertheless, direct medical control is usually invaluable for notification of a receiving facility for treatment room and staff preparation when critical or potentially critical patients are being transported.

Agencies and organizations involved in EMS development and oversight are listed in Table 190-2.

OUT-OF-HOSPITAL MEDICAL CARE AND CONTROVERSIES IN MANAGEMENT

Airway Support and Respiratory Emergencies

Interventions

Respiratory complaints account for a significant number of EMS responses. Basic measures to control and support a patient's airway include manual maneuvers (e.g., chin lift or jaw thrust), oral and nasopharyngeal devices, and bag-mask ventilation. At a more advanced level, interventions may include use of extraglottic-type airway devices (e.g., Combitube, laryngeal mask airway, or laryngeal tracheal airway), which have been shown to enable faster placement and to provide improved minute ventilation. Studies have shown that basic-level EMTs were able to successfully place laryngeal mask airways in simulated arrest models and also demonstrated an improved minute ventilation with these devices compared with bag-valve mask ventilations.[47,48] Similar studies have demonstrated that laryngeal mask airways are more successful than endotracheal intubation for paramedics because they provide a faster technique, require fewer attempts for successful insertion, and improve ventilation.[49]

Commonly used by air medical services, drug-assisted intubation (DAI) and rapid sequence intubation (RSI) procedures are well established in ground transport services, despite a lack of supporting evidence. Although many services routinely perform intubation, several studies have challenged the effectiveness of out-of-hospital intubation, particularly in view of an alarming incidence of esophageal intubation in some systems and poor outcomes with the use of RSI for head-injured patients.[50-53] One prospective, randomized study of pediatric out-of-hospital airway management concluded that in the urban setting, bag-mask ventilation may be superior to intubation in certain groups of patients.[54] Although controversy exists and the debate will continue, most would agree that to have a successful airway management program, the educational and quality management component must be meaningful and should be as comprehensive and compulsive as possible.[55] For programs using DAI or RSI procedures, the experiential component should include operating room time and simulator sessions. Ideally, training would also occur in an emergency department setting where patients requiring emergent intubation would potentially have the full complement of confounding variables (e.g., combative status, full stomachs, blood and vomit in the airway). Such training may be difficult or impossible to achieve, particularly ongoing maintenance of skills sessions, especially in rural communities. Unless EMS systems perform a large number of intubations, with at least several intubations per provider per year, use of an extraglottic device for tracheal intubation should be strongly considered.[56]

Traditionally used in the hospital, continuous positive airway pressure (CPAP) is intensifying in the out-of-hospital setting. The effectiveness of out-of-hospital use of CPAP has been demonstrated; however, patient outcome studies have been limited.[57,58] Out-of-hospital use would require strict protocols that outline such variables as indications and contraindications, clinical applications, mental status assessment, hemodynamic status, and mechanisms for transfer of the patient at the hospital.

Medications

Most advanced programs have adopted the use of clinically proven medications for bronchospasm, chronic obstructive pulmonary disease, and anaphylaxis, but no studies have demonstrated benefit to administration of these medications in the out-of-hospital environment. Whereas some studies might be considered unethical (e.g., an out-of-hospital study of epinephrine for anaphylaxis), others (e.g., out-of-hospital use of beta$_2$-agonists or steroids for asthma, or loop diuretics for pulmonary edema) could easily be performed, with the results far from certain. Pending further studies, most systems have adopted the position that these medications do not harm patients in the out-of-hospital setting, may be helpful, and may provide comfort and clinical improvement for most patients experiencing varying degrees of respiratory distress. The overhead for training and maintenance of knowledge related to these additional, probably unnecessary medications is rarely considered.

Cardiovascular Emergencies

Interventions

Early research demonstrated the effectiveness of early defibrillation for termination of ventricular fibrillation and improvement of survival rates from sudden cardiac death.[59] Advances in technology have improved such that defibrillators, traditionally used by paramedics, are now used by a variety of public safety responders and bystanders. Public access defibrillation programs are continuing to be implemented throughout the country, with devices being placed in high-volume, populous, and secluded areas such as airports and airplanes, casinos, churches, office buildings, and other locations identified as high risk for resuscitation.[60] The acquisition and transmission of out-of-hospital 12-lead electrocardiograms is becoming more prevalent as well. Although it is expensive to implement, several studies have revealed minimal delays in scene time while the electrocardiogram is obtained and a shorter time to intervention (thrombolytic administration or catheterization laboratory admission) by use of this technology.[61,62]

A factor now recognized to improve survival from cardiac arrest is uninterrupted or minimally interrupted chest compressions.

www.ketabpezeshki.com 66485457-66963820

Each interruption of compressions (e.g., while intubating, checking for pulses, analyzing rhythms) decreases coronary perfusion pressure, which in turn decreases cellular respiration.[63] This same tenant may be used for prearrival telephone CPR instructions in that more bystanders may be willing to perform continuous chest compressions if artificial ventilations were discarded.

Although the statistics for cardiac arrest survival across the United States are dismal, those who do survive may suffer some degree of hypoxic encephalopathy. Recent evidence suggests that with cooling of patients who achieve a spontaneous return of circulation after cardiac arrest, especially with ventricular fibrillation as the initial rhythm, higher survival rates and level of neurologic functioning are achieved.[64,65] The explanation may be due to several mechanisms, including a decrease in neuronal cell oxygen consumption, cell membrane protection, slowing of degradative reactions resulting from reperfusion, and limiting of acidosis.[66] International guidelines now call for the institution of hypothermia for patients who are resuscitated from cardiac arrest, and many out-of-hospital systems have implemented protocols that may include administration of chilled saline, sedation, or neuromuscular blockers in coordination with receiving hospital emergency departments.

Medications

Traditional cardiac medications recommended by advanced cardiac life support are used by most ALS systems. Recent investigations involving amiodarone as an out-of-hospital agent to terminate refractory ventricular fibrillation have resulted in higher survival rates to hospital arrival; however, improvement in survival to discharge is still not significant.[67] Whether amiodarone should replace lidocaine for out-of-hospital ventricular fibrillation requires further investigation, although many systems have already made this expensive change. The use of out-of-hospital fibrinolytic agents for acute ST elevation myocardial infarction has not gained wide acceptance and may be a useful intervention only for systems having prolonged transport times or if hospitals may not have catheterization or intervention facilities available. Future recommendation for out-of-hospital use of these agents remains speculative.

Traumatic Emergencies

Interventions

Interventions for specific medical emergencies, such as cardiac arrest (i.e., defibrillation, intubation, intravenous line, and medication administration), may be effectively performed while on the scene or before hospital transport. Alternatively, it is widely accepted that most interventions for traumatic injuries should be performed en route to the hospital, and all efforts should be extended to reduce on-scene time. Only two interventions should be considered for critical injuries, control of the airway to reverse hypoxemia and to prevent aspiration and stopping of uncontrolled hemorrhage. Although it is a routine part of prehospital trauma care, tracheal intubation is not known to be beneficial for severely injured patients.[68] There are many potential drawbacks to prehospital intubation for major trauma. To be successful, paramedics should rapidly place the endotracheal tube correctly, assess and confirm the placement, and secure the tube to prevent displacement. In addition, providing the correct minute and tidal volumes is equally important. Inadvertent hyperventilatory rates may impair cardiac output and cause further tissue damage. Patients sustaining blunt head injury pose special problems that should be expeditiously addressed and resolved. Intubation is but one means of providing ventilatory assistance and airway protection, but misadventure, complications, and improper postintubation care may negate these potential benefits. Attempting to intubate head-injured patients may result in dental or soft tissue damage in those patients with clenched teeth, and intracranial pressure may be exacerbated from an intact gag reflex or from subsequent regurgitation. Studies on the use of RSI in head-injured patients reveal that patients experience significant hypoxia and bradycardia during the procedure, and outcome is actually worse.[46] Thus the role of RSI in prehospital airway management in trauma patients is in question, just as it is for medical patients. The use of extraglottic airway devices may be a promising addition to prehospital airway management in trauma patients. Routine use of prehospital intubation is not recommended unless the system can ensure that its providers meet the standards previously outlined. Emergent hemorrhage control is also essential in reducing mortality in severe trauma. For internal bleeding, limiting of total prehospital time and transfer to definitive surgical care are paramount. Recent evidence on the battlefield has demonstrated the effectiveness of tourniquet application to extremity wounds. These devices may have application in the civilian setting, are quick and easy to apply, and do not result in the complications once thought to exist.[69]

The issue of intravenous fluid administration has gained controversy over the years. High-volume intravenous fluid for hemodynamic instability resulting from traumatic injury has traditionally been the accepted standard in most out-of-hospital care systems. Previous data, however, support a paradigm shift to restrictive or hypotensive resuscitation for penetrating truncal injuries. Restoration of hemodynamic stability with fluid resuscitation before definitive surgical hemostasis may lead to increased morbidity.[70] The use of prehospital intubation and high-volume crystalloid infusion bears unfortunate similarity to the widespread, unsupported adoption of the pneumatic antishock garment in the 70s and 80s. Despite lack of evidence of benefit and significant evidence of harm or potential harm, these practices are notoriously difficult to discontinue once adopted.

INTERFACILITY AND SPECIALIZED TRANSPORTS

Transportation between health care facilities may occur for several reasons, including patient preference, unavailable diagnostic or therapeutic resource availability at the transferring facility, and managed care requirements that patients be cared for in predesignated hospitals after stabilization. Hospital corporations engaged in networks or alliances that share resources and services depend on interhospital transport systems to convey patients to allied institutions for specialized tests or procedures. Likewise, critical patients admitted to less specialized facilities may need to be transferred to tertiary care or designated trauma centers. Whereas long-distance transports may be best accomplished by air medical services, regional or local transports should use ground systems. These may be provided by either local EMS resources or those owned and operated by the hospital.

Interfacility transfer of patients that is medically indicated must fall under a set of requirements referred to as the Emergency Medical Treatment and Active Labor Act.[71] Although the EMS system providing the transport plays a key role, these guidelines primarily involve particular information and obligations that must be satisfied by the transferring and receiving facilities before transfer. An unstable patient should not be transferred to another facility at the request of a managed care organization unless the transferring hospital is incapable of providing standard care and the receiving hospital does have the capability to manage the condition and foreseeable complications. Box 190-1 lists various requirements that should be completed before a patient is transferred to another facility.

www.ketabpezeshki.com 66485457-66963820

Box 190-1 EMTALA Requirements for Patient Transfers

Complete certification (risks and benefits) of transfer
Informed consent obtained from the patient or family
Appropriate transportation (equipment and personnel) arranged
Treatment and stabilization performed
Acceptance from receiving facility ensured
Appropriate patient care data sent (fax or with patient)

EMTALA, Emergency Medical Treatment and Active Labor Act.

Depending on the patient's condition, specialized transport services may function at the BLS or ALS level, providing emergency or nonemergency transportation. Patient transfers considered ALS may include interhospital (either emergency department or intensive care unit) neonatal or high-risk infant, critical cardiac, and trauma transports. Personnel configuration depends on system design and level of care provided. Many programs use a nurse-paramedic combination. Patients requiring specialized care may need the services of specifically trained individuals, such as respiratory therapists, neonatal nurses, or other specialized critical care personnel. The presence of a physician is not mandatory but may be useful in selected cases.

As with any EMS activity, all interfacility transports should be reviewed for appropriateness of transfer and medical care provided. In 1993, the Practice Management Committee of the American College of Emergency Physicians updated the 1990 policy statement on interfacility transfers.[72]

THE FUTURE

Providing quality, efficient, and responsible health care to the right patient, in the right setting, at the right time will be a laudable objective for any system, but there is a need for research to demonstrate which interventions are conducive to better patient outcome. As the call volumes increase, it is imperative that systems focus on those interventions, from both the training and health care delivery perspectives, that are known to be of benefit.

Acknowledgments

The author again wishes to express thanks to Joey, Alex, and Marty for their love and support.

CHAPTER 191

Air Medical Transport

Howard Rodenberg, Ira J. Blumen, and Stephen H. Thomas

PERSPECTIVE

The history of air medical transport (AMT) dates to before World War I, when the French evacuated soldiers from Serbia using airplanes as ambulances as early as 1915. The first recorded use of a U.S. military air ambulance was in 1918 when an airplane was converted to accommodate a litter patient in the rear cockpit. During World War II, more than 1.1 million sick and wounded soldiers were airlifted to the United States during the last 3 years of the war. The Korean War introduced the helicopter to AMT, and more than 20,000 battlefield medical evacuations were flown during the conflict. During the Vietnam War, Operation Dustoff transported nearly 1 million of the injured from the front lines to care.

The impact of AMT on the wounded soldier was clear. During World War II, the average time from injury to definitive care was 6 to 12 hours, with a mortality rate of 5.8%. In Korea, the time was 2 to 4 hours, with 2.4% mortality. In Vietnam, the time was 65 minutes, and mortality was less than 1%.[1] Encouraged by the military experience, civilian AMT in the United States was propelled by the 1969 start of the first hospital-sponsored, fixed-wing air medical program. The first civilian helicopter emergency medical services (HEMS) program in the United States was established in 1972.

AVIATION PHYSIOLOGY

A working knowledge of aviation physiology is vital to understanding of the effects of AMT on pilots, medical personnel, and patients.[2]

Boyle's Law

The cornerstone of aviation physiology is Boyle's law, which states that the volume of a unit of gas ("unit" defined as a specific number of molecules) is inversely proportional to the pressure on it. In concrete terms, Boyle's law means that as altitude increases and atmospheric pressure decreases, the molecules of gas grow apart, and the volume of the gas expands. With descent (increasing atmospheric pressure), the molecules are condensed, and gas volumes contract.

Physiologic difficulties from expansion and contraction of gases within the closed spaces of the body may occur with altitude change. Squeeze injuries from contraction of air and associated soft tissues within closed cavities occur on descent and are common causes of barotitis, barosinusitis, and toothache. Reverse squeeze injuries occur on ascent, as decreasing barometric pressure leads to an increased volume of the air trapped within the space, exerting pressure on structures. Ascent injuries can include conversion of a simple pneumothorax into a tension pneumothorax or rupture of a hollow viscus by expansion of intestinal gas. The operation of medical equipment containing closed air spaces, such as intravenous tubing and pumps, air splints, ventilators, and endotracheal tube and laryngeal airway cuffs, may also be affected by altitude.[3-7]

Boyle's law is predominantly responsible for the presence of hypoxia at altitude as there are fewer molecules of oxygen present per volume of inhaled gas at altitude. Similarly, dispersion of molecules of water vapor within a gas volume is seen at height, and "dry air" results.

Charles' Law

Charles' law follows from the volume effects of Boyle's law. It notes that as the volume of a unit of gas rises, the temperature of that volume falls. The molecular dispersion seen with increases in gas volume at altitude (Boyle's law) means there is less chance of molecular collision with resulting generation of heat. Charles' law explains why the ambient temperature decreases with increased altitude.

Dalton's Law

Dalton's law states that the total barometric pressure at any given altitude equals the sum of the partial pressures of gases in the mixture ($P_t = P_1 + P_2 + P_3 \ldots P_n$). Whereas oxygen still constitutes 21% of the atmospheric pressure at altitude, Boyle's law notes that each breath brings fewer oxygen molecules per breath to the lungs, and hypoxia results (Table 191-1). The clinical effect of Dalton's law is manifested as a decrease in arterial oxygen tension with increasing altitude.

Initial physiologic responses to hypoxia include tachypnea and tachycardia. With prolonged exposure, oxygen supply to the brain becomes insufficient to support cerebral metabolism. Progressive cerebral hypoxia causes headache, nausea, drowsiness, fatigue, unconsciousness, and death. Although the onset and severity of symptoms may vary with individuals, no one is exempt from the effects of hypoxia.

Henry's Law

Henry's law states that the mass of gas absorbed by a liquid is directly proportional to the partial pressure of the gas above the liquid. Henry's law has its most familiar applications in diving medicine, in which the increased pressure exerted on gases in the body at depth forces the gases into solution in the bloodstream. Rapid ascent from depth causes the gas to come out of solution within the bloodstream, resulting in decompression sickness.

www.ketabpezeshki.com 66485457-66963820

Table 191-1 Effects of Altitude on Oxygenation

ALTITUDE (ft)	BAROMETRIC PRESSURE (mm Hg)	Po_2 (mm Hg)	PAO_2 (mm Hg)	$Paco_2$ (mm Hg)	OXYGEN SATURATION (%)
Sea level	760	159.2	103.0	40	98
8,000	565	118.4	68.9	36	93
10,000	523	109.6	61.2	35	87
15,000	429	89.9	45.0	32	84
18,000	380	79.6	37.8	30.4	72
20,000	349	73.1	34.3	29.4	66
22,000	321	67.2	32.8	28.4	60

PAO_2, partial pressure of alveolar oxygen; $Paco_2$, partial pressure of arterial carbon dioxide.

Henry's law does not carry the same weight in aviation medicine because the degree of change in atmospheric pressure per unit of distance is considerably less than the degree of change in water. However, sudden decompression at altitude may result in dysbarism.

Additional Stresses of Flight

Other stresses of flight that can affect the patient or crew include temperature fluctuations, dehydration, noise, and vibration. Temperature changes may produce increases in metabolic rate and oxygen consumption. As noted, at altitude the moisture per volume of air falls. Fluid intake should be monitored carefully during transport, and all patients should receive humidified medical oxygen. Noise and vibration represent the most ubiquitous stresses encountered in AMT, and both may interfere with patient care or the function of medical equipment. Hearing protection should be worn at all times during aircraft operations by patient and crew. Exposures to environmental extremes may result in fatigue, motion sickness, disorientation, ear damage, and deterioration in task performance.

PRINCIPLES OF AIR MEDICAL TRANSPORT SYSTEMS

Administrative Structure

Air medical services may take several forms. Despite a tremendous growth of operations in the past 20 years, the most common type of HEMS program in the United States remains the hospital-sponsored operation transporting patients from outlying referral centers or accident scenes to tertiary care centers. A single hospital or a consortium of institutions may sponsor these flight programs. In 2011, there were more than 220 dedicated HEMS programs operating more than 750 dedicated aircraft throughout the nation.[8] Approximately 54% of the programs were hospital sponsored, and the balance were operated by privately owned or publicly traded companies. Whereas these for-profit companies represent 46% of the programs, they operate more than 61% of the dedicated helicopters in the United States.[8] Public service agencies may also sponsor air medical services or partner with private companies; vehicles used by these programs are often multifunctional aircraft that serve in medical, search and rescue, fire suppression, and law enforcement roles. The Military Assistance to Safety and Traffic (MAST) program operated by the U.S. Armed Forces provides additional HEMS resources to the community,[9] but in recent years their role for civilian support has been generally limited to Hawaii and Alaska.[9] Together, the public service and MAST helicopters add more than 120 additional aircraft available for patient transport.[8] There is no accurate accounting of the number of fixed-wing air ambulance companies or airplanes. Although some hospitals do sponsor fixed-wing AMT, it is more common for these programs to be private fee-for-service operations.

Types of Missions

Air medical missions may involve primary or secondary response. Primary responses ("scene flights") are responses in which the aircraft serves as the sole means of patient transport to a receiving facility. Aircraft involved in secondary responses—interfacility transport—move patients from outlying hospitals to facilities offering higher levels of care. AMT missions may also be classified according to the level of care provided. This may be critical care transport, specialty care transport, or advanced or basic life support.

Air Medical Aircraft

Although the ground ambulance remains the primary means of out-of-hospital and interfacility patient transport, the use of the air ambulance has grown significantly since the 1970s. No one aircraft is ideal for the needs of all air medical programs or patients.

Helicopters (Rotor-Wing Aircraft)

The helicopter offers several advantages over other transport vehicles. Traveling "as the crow flies" at speeds of 120 to 180 mph, helicopter transport time is often 75% less than that for an equivalent distance by ground. The service area of helicopter programs is generally up to 150 to 200 miles from its base of operations. Rotor-wing aircraft have the ability to avoid common traffic delays and ground obstacles and can fly into locations that may be inaccessible to other modes of travel. Helicopter landing zone requirements are a disadvantage compared with ground ambulances but offer an advantage over the airport requirements of airplanes.

Disadvantages to HEMS include noise, vibration, thermal variances, and other stressors on patients and crew exaggerated by rotor-wing flight. Weather considerations may significantly limit the availability of helicopter transport. In smaller aircraft, cramped spaces and weight limitations may limit the number of patients, transport personnel, or equipment that can be carried. This may sometimes compromise optimal patient care (Fig. 191-1).

Many helicopter programs permit flight only under visual flight rules. When the weather conditions (ceiling and visibility) fall below established program minimums, a program may decline to undertake a transport for safety reasons. However, an increasing

www.ketabpezeshki.com 66485457-66963820

Figure 191-1. Confined spaces within helicopters may make it more challenging to perform procedures. (Photograph courtesy Ira Blumen, MD.)

number of programs are equipping their helicopters and training their pilots for instrument flight rules (IFR) to allow safe travel in less favorable weather conditions. IFR flight may facilitate use of fixed locations, such as hospital helipads, but it does not facilitate travel to the scene of illness or injury.

Airplanes (Fixed-Wing Aircraft)

Although rotor-wing missions attract more media attention, fixed-wing flights constitute a significant portion of AMT operations. Fixed-wing aircraft provide increased range, greater speed, and often more patient, crew, and equipment capacity than do rotor-wing vehicles. The decreased cabin noise and turbulence creates fewer patient management problems, and pressurization combats the physiologic impact of altitude. Fixed-wing operations are limited to areas that have airports with runways of appropriate length or condition and refueling facilities. During fixed-wing transports, patient transfers require multiple vehicles to go from hospital to airport and back.
